The latter may be visualized from considerations of heat absorption in the furnace by radiation. Consider a furnace temperature of, say, 2800 deg. and a flue temperature of, say, 550 deg. under a certain operating condition. If a given quantity of air is admitted into the flue after the gas has passed over the heating surface of the boiler, the flue temperature may be dropped to, say, 500 deg. If a 50-deg. drop were to take place in the furnace, it would diminish the absorption all along the line on its way through the boiler. Consequently, from energy considerations the lesser absorption will be reflected in a higher flue temperature. The final temperature would be above 500 deg. In both cases the flue-gas reading would be substantially the same.

The paper is a valuable contribution in cases where comparable results are desired in the same or similar plants. Thus when one is seeking to improve plant economy, even though there be inaccuracies in the samples of flue gas and temperatures, the fact that all tests are made alike will tend to wipe out errors in measurement. The results will be comparable, although not accurate in the absolute sense. The comparatively low cost at which tests can be made in accordance with the scheme proposed by the author should find wide application.

B. G. Worth.[7] Two aspects of this paper impress one immediately. First, the close agreement of efficiencies determined simultaneously by both methods is quite remarkable, particularly when one considers the numerous factors involved. This suggests that the heat-balance method is perhaps more important as a means of checking the straight coal-and-water method than as an alternative method of easier application. And many will be hard to convince that the heat-balance method is, in fact, easier, even for larger plants.

The second aspect is the small variations in efficiency between the separate tests of each series. This variation, from recollection, was about 5 per cent, which appears to be a satisfactory result. If the coal-and-water method can come so close to the losses method, does not this rather negative the difficulties imputed to the coal-and-water method?

Tests are conducted generally for one or more of three reasons: to check apparatus-performance guarantees, plant-performance tests (often as basis for improvement programs), and for data on continuous operating cost.

In the case of performance tests the lines are often closely drawn and a few per cent, plus or minus, may make a great difference, depending on the liberality and practicality of the parties to the contract. In these cases absolute values are necessarily striven for.

With plant performance absolute values are not so important, for the usual use of such tests is to continuously improve the economy of the plant. If the results are inaccurate, but the inaccuracies are of the same relative nature, efforts toward improvement will be about as effective as if the results were absolutely true. In such cases it is a great deal better to have a relatively inaccurate test method which is actually used than a fine method which is seldom utilized because of its difficulties. It has been well said that "sustained mediocrity is preferable to intermittent perfection."

It is the writer's belief that there is a tendency to attach too much importance to the last per cent. No matter how carefully apparatus may be prepared and calibrated and samples of coal and ash taken, variations will occur, and sometimes they will cumulate and sometimes average out. This is shown most strikingly by the two sets of tests shown in the paper. A fair evaluation of the results would be a mean drawn through the evidently representative tests and throwing out the ones obviously wide of the mark.

If accuracy is considered a practical and not an academic matter, it will follow from inspection of the two sets of tests shown in the paper that either method of test has about equal chances of giving an acceptable result.

With this point conceded, the question of choice resolves itself into which method is the easier. This is a real problem in very large plants, and the difficulties of the coal-and-water method are, as the author stated, the reason for working out the losses method. But with smaller units, such as are generally found in industrial plants, such does not appear to be the case, and for such plants the writer is strongly of the opinion that the coal-and-water method is the easier, if not the better.

Just what plants the author had in mind is unknown, but it would seem that in practically all plants it is easier to measure coal than ash. Coal is carefully weighed in all plants, large or small, making any pretense of efficient management. Lack of care in this direction is certainly not imaginable in large public-utility plants, since coal is the major operating expense, and is moreover part of the ultimate overall basis of efficiency of the station, viz., coal per kilowatt-hour. Refinement in weighing coal should certainly not be difficult to attain in public-utility plants. With moderate-sized industrial plants it is actually not so easy, for many executives who will spend money freely on certified accountants and the like will balk at the cost of coal-and-water measuring equipment that would pay for itself in a year. There is, however, nothing difficult about coal weighing, and any well-designed plant should have the apparatus for such weighing built into the plant at the start.

Measuring and sampling ash is more difficult, and changes in composition are more likely than in coal. For ash weighing special apparatus must be provided in most cases, and is a dead loss, for it is not likely to be used in operative tests. When ashes are dumped into trucks, they may be weighed on truck scales with reasonable accuracy, but who is to say how much water was used to wet them before dumping into the truck. The same applies to dumping into railroad cars. But what about ashes which are disposed of by a water conveyor system. What about ash slagged off? To handle these seems a great deal more trouble than coal weighing. Again, changes in ash composition may take place very readily if the fireman is not vigilant. How is one to catch such changes? Of course, all ash inaccuracies are much less important than coal inaccuracies due to the fact that ash is only a small fraction of coal. Ash-measuring difficulties, however, appear formidable compared with the ease of measuring coal.

The real difficulty in the straight evaporative test is to measure the water. This can be easily done where feed temperature is low, but certainly is difficult when temperature is high. But with the possibility of measuring and checking steam output against feedwater and by various calibration methods determining the amount, character, and sign of instrument error, such determinations should be brought well within the reasonable error of the whole test. It is not easy to set up such accurate feedwater determination, for much patience and care are required to get flow meters to work dependably, but many engineers will agree that the effort and expense of such a proceeding should not be as great as that required for the heat-balance method.

Think of the difficulties in accurately measuring gas flow,

[7] Vice-President, Walter Kidde & Co., New York, N. Y. Mem. A.S.M.E.

gases composition, actual radiation, carbon loss up stack, etc.

Speaking from the standpoint of the moderate-sized industrial plant, it would seem to the writer that the heat-balance method is not justified in such causes.

In the cases of large plants where large sums of money, both in first cost and operation, are involved, the practical view would seem to be that both methods together are none too accurate, and that the author's loss method forms a very valuable check on the direct determination. It is a question whether it constitutes a good substitute.

JOHN BLIZARD.[8] The writer has read the paper with much interest. The author is one of the leading authorities on the subject and has devoted much time to developing means for measuring as accurately as possible the losses of energy from steam-generating equipment.

He gives a well-known and simple equation for determining the ratio of the mass of dry-flue gases to the carbon in that gas. This ratio may be represented in a still simpler form when the carbon monoxide is negligible.

This simple form is:

$$\frac{\text{Lb. dry gas}}{\text{Lb. carbon in gas}} = \frac{240}{CO_2} + 1$$

This equation is less accurate than the one given in the paper, but it will be found to be sufficiently accurate for almost all ordinary purposes.

Since the heat content of a wide range of steam coals is 18,000 B.t.u. per lb. of carbon, a very simple and useful expression may be derived from the foregoing equation to represent the heat content of the dry-flue gases per cent of the heat in the fuel burned. It is:

$$\left[\frac{0.32}{CO_2} + 0.0013\right][t_2 - t_1]$$

This will give somewhat too low a heat content for some of the low volatile coals, but its simplicity and reasonable accuracy warrant its frequent use.

The expression for representing the total heat of the steam in the flue gases may be expressed by:

$$1090 + 0.46\, t_2 - t_1$$

instead of by the expression given in the paper.

The value given here is the heat content of steam at 1 lb. absolute pressure, which is about the pressure of the steam in the flue gases.

AUTHOR'S CLOSURE

Mr. Frost has brought up several points. Unquestionably the sampling of ash from large stokers is a difficult problem. Where the stoker has a large ash chamber, the test should be prolonged or the stoker at least should be operated under test conditions long enough to insure a representative sample of ash. If the plant operator is willing to run a weighed-coal test for a period of 96 hours to reduce the error due to judging coal in the fuel bed, it should not be asking too much to have the heat-balance test prolonged to 12 hours to insure a representative sample of refuse.

The two expressions $\frac{\text{B.t.u. of coal} - \text{losses}}{\text{B.t.u. of coal}}$ and $1 - \frac{\text{Losses}}{\text{B.t.u. of coal}}$ are, of course, identical. The term "B.t.u. of coal" is just as much a direct factor in one as in the other. By substituting actual values and varying the B.t.u. of coal by 150, it will be seen that there will be an error of 0.25 and 0.21 per cent, respectively, for 12,000 and 14,000 B.t.u. coal. By using equivalent values in Mr. Frost's expression for the weighed-coal-and-water test efficiency, it will be seen that a 150 B.t.u. error in the heat value of the coal will cause an error of 1 per cent and 0.9 per cent, respectively, for 12,000 and 14,000 B.t.u. coal.

Mr. Markson's figures of 4 to 14 per cent "unaccounted-for" include an unmeasured loss of carbon carried up the stack with the flue gases. This item of the losses is generally overlooked in stoker tests. Even though the stack may appear clear, a considerable amount of cinder may be discharged from it. We often feel the "egg shells" under our feet when we walk around a stoker-fired plant. If this loss were as visible at the stack outlet as a similarly large loss in a pulverized-coal-fired boiler would be, it would receive more attention.

While this cinder loss is more difficult to determine than the flue-dust loss from a pulverized-coal-fired furnace, it is by no means an impossible task. The cinders are comparatively large particles and tend to segregate in the ducts. A vertical passage should be selected for the location of the sampling point or points. With ordinary care this cinder loss should be determined with the degree of accuracy claimed—namely, 25 per cent.

Mr. Brooks takes exception to the limits of error claimed for the various items of the losses. It has been assumed that painstaking care has been taken in the various measurements involved. The wide margin of cost between heat-balance tests and weighed-coal-and-water tests justifies this care. It is believed that with due precaution the measurements can be made within the degree of accuracy ascribed. The two series of tests plotted in Figs. 6 and 7 indicate such precision of measurement.

The specific losses mentioned by Mr. Brooks are the loss due to unburned combustible and the radiation loss. The accuracy ascribed to these losses in the paper are 20 per cent and 25 per cent, respectively. These represent rather liberal allowances for error. In cases where the loss due to unburned carbon is as high as 20 per cent, there is of course a possibility of a serious error in its measurement. Such a high loss, however, surely would manifest itself in some easily discernible way. Such high unaccounted-for losses are of rather infrequent occurrence. At least, few tests showing such high values for this item have been reported. A large "unaccounted-for" loss is more of a reflection on the accuracy of test methods than a small negative "unaccounted-for." If radiation has been closely estimated, the unaccounted-for loss consists almost entirely of errors. As these errors may be plus or minus, the unaccounted-for loss may be positive or negative. The fact that it is usually positive indicates a constant error in some measurements. Such an error may occur in the measurement of flue-gas temperature. This determination is usually in error on the low side due to radiation from the measuring instruments to the cooler walls of the duct.

The radiation loss from boiler settings is smaller than commonly assumed. There are plants now operating in which 1,000,000 lb. of water are evaporated hourly. This represents a coal consumption of approximately 100,000 lb. per hour. If 1 per cent of the heat generated is lost by radiation, this corresponds to the burning of 1000 lb. of coal per hour at 100 per cent efficiency to heat the boiler room. In any boiler room, if the air in the room is changed at the rate required for combustion, which is usually the case, the temperature of the boiler room would be about 40 to 50 deg. over the outside air temperature. This corresponds approximately to actual winter conditions. In the summer months this release rate would result in unbearable room temperatures.

The rate of heat release in the steam radiator, which represents an attempt to radiate as much heat as possible, is from 250 to

[8] Head, Research Department, Foster-Wheeler Corporation, New York, N. Y. Mem. A.S.M.E.

300 B.t.u. per sq. ft. per hour. In the boiler setting, where everything possible is done to reduce the radiation and where average surface temperatures do not exceed those of a steam radiator, the rate of radiation surely will not be higher. Extremely high percentage radiations may occur at very low boiler ratings. Under banking conditions the radiation may approach or exceed 100 per cent. These conditions, however, are not representative of normal operation and surely not of test conditions.

Mr. Adler points out that weighing coal and water seems the more direct method and has a stronger appeal. This is largely a psychological matter. We like to deal with matter that we can see and feel. Modern physical measurements, however, deal largely with the invisible. We measure and weigh atoms and even electrons and measure visible and invisible light waves. It is largely a matter of getting used to the less familiar methods and using new tools.

While the location of air leaks may have an effect on magnitude of the dry-gas loss, as Mr. Adler states, it does not affect the measurement of the loss. The analysis of the gas and its temperature is a definite measure of the dry-gas loss, providing of course that the sample of gas and its temperature are taken at the same cross-section of the flue.

Mr. Worth points out the close agreement of results between the efficiencies obtained by weighed water and coal and by the heat-balance methods for the two groups of tests plotted in Figs. 6 and 7. He brings out the point that this is an indication of accuracy for the weighed-coal-and-water tests as well as for the heat-balance tests.

The two series of tests were selected because, in each case, considerable pains and expense were taken to install accurate water-weighing devices. The conditions at the plants enable all the water to be weighed to the system at moderate temperatures. Moreover, the amounts to be handled, while large, were not excessive. In short, the conditions at those two plants were in every way favorable for the accurate determination by weighing of all the water fed to the boiler. These two plants are unusual in this respect. In neither plant were the conditions for measuring losses more favorable than they would be in most other plants.

The question as to which is easier, the heat-balance method or the weighed-water-and-coal method, does not need be considered. Speaking paradoxically, when there is a choice, there is no choice; both methods should be used. There is no doubt that the heat-balance method is less expensive. While it may not be difficult in small plants to weigh coal and water, such plants are often limited in the amount of money they can spend for the purpose of testing, and the heat-balance method must therefore be used.

The weighing of ash is more difficult than the weighing of coal, because there is usually no provision for the routine weighing of ash as there is for coal. It is only necessary to establish rates. The heat balance test can be completed in a period not to exceed 6 or 8 hours. In small plants the entire ash for this period can be collected and weighed in wheelbarrows or ashcans without excessive labor. Larger plants are usually equipped with clinker grinders that deliver ash at uniform rates. In this case the discharge of ash for one hour can be collected and sampled. The test should be long enough so that the ash during this hour would result from burning the coal under the conditions of the test.

In pulverized-coal plants only a comparatively small percentage of the ash is deposited in the furnace. This can be weighed or even estimated with a degree of accuracy that will not introduce a serious error in efficiency. As a large part of the ash goes up the stack, the loss represented by this portion can be determined from the flue-dust sample. This stack loss also exists in stoker-fired boilers, and if neglected, as is commonly the case, appears in the item "unaccounted-for."

FSP-52-34

The Performance of Modern Steam-Generating Units

By C. F. HIRSHFELD[1] and G. U. MORAN[2], DETROIT, MICH

There has been much speculation during the past as to those factors which seem to be most responsible for steam-generating-unit outage. This is a question which always arises when a plant is being designed for a certain capacity factor, where the reliability or availability of the boiler units must be accurately foreseen.

Some have held that the outage increases directly with the severity of use. Others contend that the method of burning the fuel has a definite bearing on reliability. Others still have set different values for unit reliability on different kinds of fuel.

As the probable availability of units operating under certain conditions is a matter of utmost importance to the power-station designer and owner, it was thought that a complete and thorough study of the facts obtaining in the power-generating industry would be of great value. With that idea in mind the authors were requested by the Central Stations Committee of the Power Division to prepare this paper.

The study was made along the same general lines as the steam-turbine investigation made by the Prime Movers Committee of the N.E.L.A. The methods used in collecting information were as nearly identical as circumstances and the character of the units studied would permit. Daily operation logs were filled out for the period of one year by the operators of some two hundred boilers scattered about the country in sixty-odd stations. The data resulting were compiled by one group of men in such a manner that the results might be readily compared.

The units have been arranged in groups or classes according to methods of fuel burning and the working steam pressures, and then numbered in order according to their average rates of evaporation. With the data arranged in such a manner it has been possible to arrive at some rather definite conclusions.

THE studies reported in this paper were made at the request of the Central Stations Committee of the Power Division of the A.S.M.E. That committee outlined briefly what it had in mind, and the authors have followed these directions in so far as it proved possible to do so.

The rapid improvement in the thermal performance of steam-operated generating stations which has occurred in the past two decades has been amply treated in the literature of this subject.[3] Another and equally important development has not been presented as adequately. Reference is made to the better use of the dollar in the design and construction of such stations. Since the cost of producing power must include, among other things, both the cost of fuel and the charges proportional to investment, it is obvious that thermal efficiency purchased at an increase of investment which exactly balanced it would be almost meaningless economically except possibly for the questionable virtue of conserving the nation's fuel supply. There might be other indirect advantages such as the release of transportation facilities by the decreased demand for fuel, release of man power for other purposes, and so on. However, the statement made will obviously hold with respect to immediate and direct results.

It is an interesting fact that the increase of thermal efficiency that has been made has not been purchased by a counterbalancing increase of investment. A real advance has therefore been made in an economic sense as well as in a purely technical one.

During the period here under discussion the wages of unskilled and of skilled labor have also increased. As both types are used in steam-power production, it is but natural to find that design has progressed along such lines that it has also resulted in a marked decrease in the number of man-hours required per unit of output.

TABLE 1 NUMBER OF UNITS INCLUDED IN THE STUDY DIVIDED ACCORDING TO THE N.E.L.A. GEOGRAPHICAL DIVISIONS

Division	Number of units	Division	Number of units
Eastern	63	North Central	2
East Central	23	Northwest	0
Great Lakes	40	Pacific Coast	7
Middle Atlantic	0	Rocky Mountain	4
Middle West	18	Southeastern	3
New England	3	Southwestern	23
Total	186		

It is not pertinent to the present paper to discuss in detail the various means by which such desirable results have been produced. Suffice it for present purposes to say that among other changes the steam-generating units have increased greatly in size, in rate of output per unit of surface, and in complexity as well as in efficiency.

Once more in a general sense, low investment is not of itself a complete criterion on the dollar side of the picture. A large investment which can be and is used, for, say, 80 per cent of each complete year during the life of a plant, may represent a better economic solution than a smaller investment made to accomplish the same result, but usable only during, say, 50 per cent of the entire year. That is, the extent to which equipment can be kept in as continuous service as existing conditions indicate to be ideally desirable is also an important measure.

Thermal efficiency is comparatively easy of proof. Investment made is merely a question of fact. The performance factor, however, is a question of experience, and any one individual's intimate experience must necessarily be limited to a comparatively small number of installations. It results that while the world now knows a lot about the thermal efficiency of steam-operated generating plants and a lot about the first cost of such plants, it knows very little indeed about the extent to which various features of design influence the ability of those plants to produce when, as, and if required.

A beginning was made in the latter field some years ago when the Prime Movers Committee of the National Electric Light Association undertook an annual statistical study of the performances of representative steam-turbine installations for the

Contributed by the Power Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

purpose of determining the extent and cause of unavoidable outages. The nature of the problem in that case was such that little could be determined with respect to the effect of the major features of design. But the facts with respect to ability to perform could be and were determined. Also, the weak parts of the rapid changes in the design of such equipment which have occurred in the past few years and in view of the economic importance of the ability of steam-generating equipment to remain on the line for very long periods of time, it appeared that such a statistical study would be desirable. The request of the Central Stations

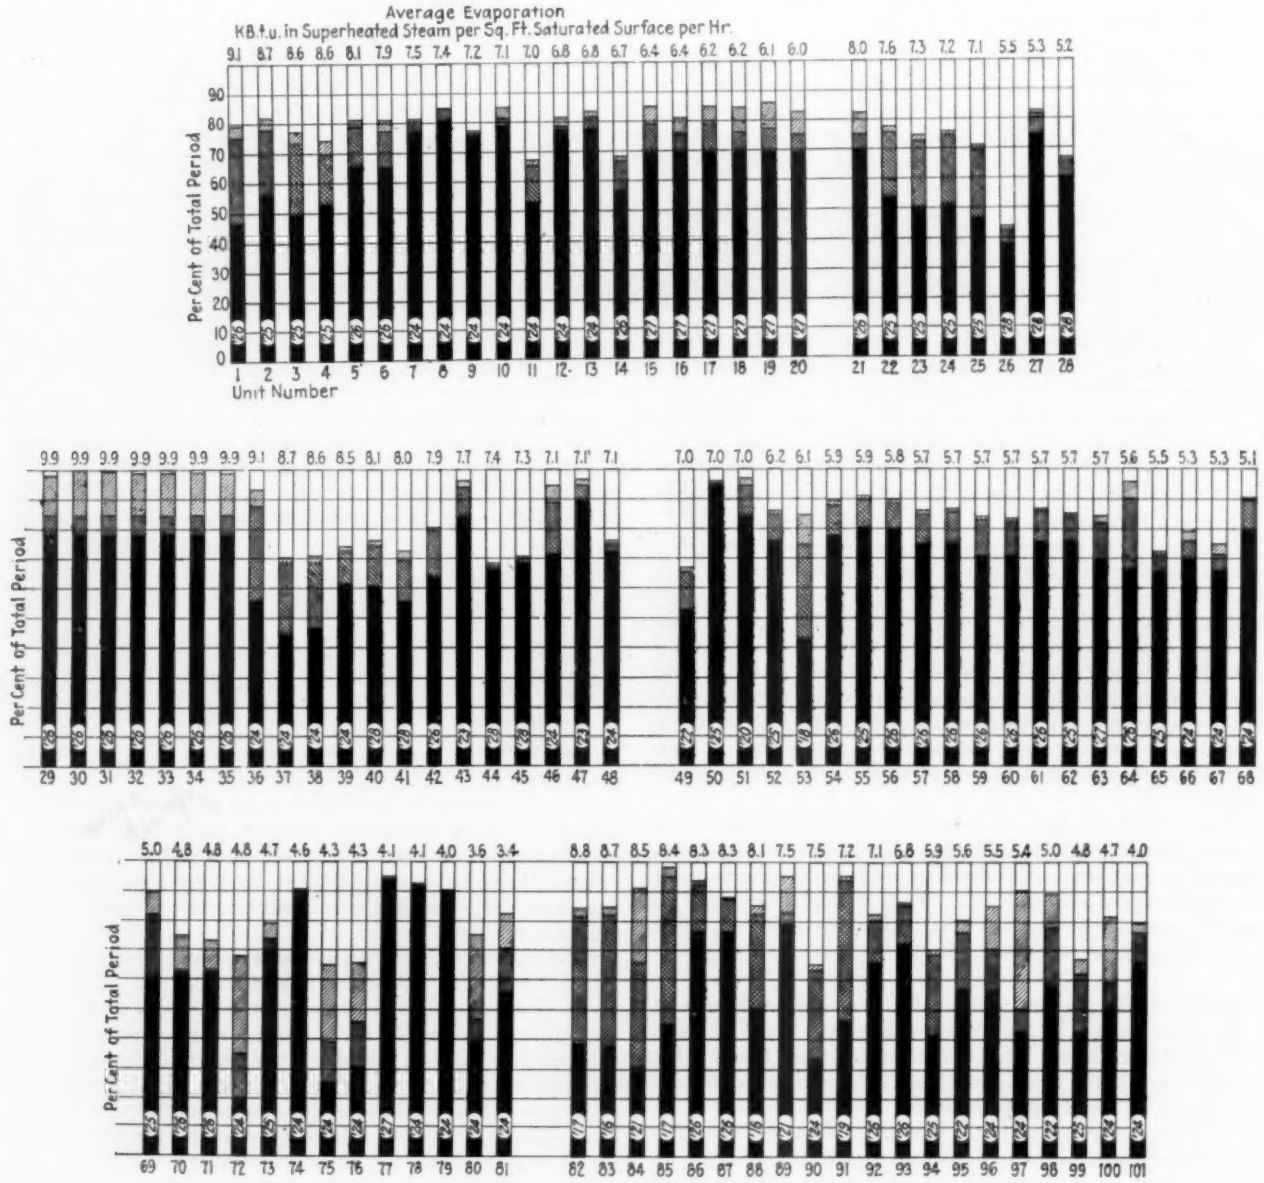

FIG. 1 RECORD OF OPERATION—STOKER-FIRED UNITS

UNITS	LEGENDS	
1–20, inc., 500 to 700-lb. pressure class	White	Crippled
21–28, inc., 400 to 499-lb. pressure class	Single hatching	Reserve

82–101, inc., 200 to 299-lb. pressure class	Black	Steaming

various assemblies were indicated, so that designers', builders', and operators' efforts could be concentrated on the weaknesses thus disclosed. A measuring stick was constructed and normal values were determined so that each individual had a means of ascertaining whether his own performance was good, bad, or normal.

No corresponding statistical studies of the performance of steam-generating equipment had been made. In view of the Committee referred to above was, in essence, a request to do just that sort of thing.

It is the hope of every central-station designer and operator that some day the steam-generating equipment may be brought to such a stage of perfection of design and construction that, when properly operated, it will have the same degree of availability for service as characterizes the modern steam turbine, attached generator, and subsidiary or auxiliary equipment.

Method Used in Making Study

The study was made along the same general lines as those of the steam-turbine investigation already referred to. The methods used in collecting information were as nearly identical as circumstances and the character of the units studied would permit. It was intended to include boilers operating in industrial plants as well as in central stations. It proved impossible to get the necessary cooperation from industrial plants, and the results herein contained apply only to central stations.

Those persons filling in the logs were requested to give the primary cause of each shutdown. The total outage for each unit was subdivided by the authors according to the reports sent in. The results of the compilation for a twelve-month period are shown in Figs. 1 to 8, inclusive, and also in Tables 2 to 4, inclusive.

Several stations, particularly those in industrial plants, did not send in reports for a period long enough to entitle them to an even footing with those reporting over the full period of twelve

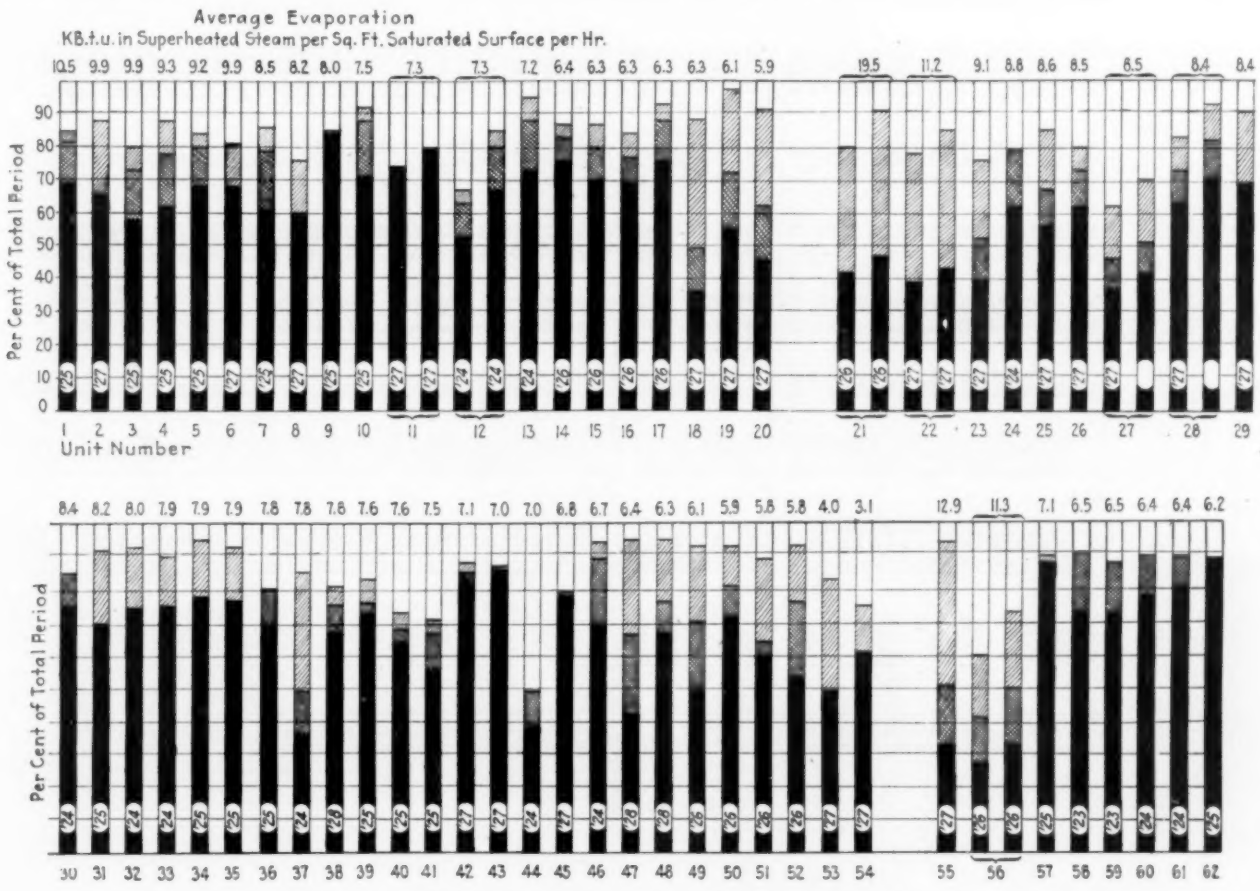

Fig. 2 Record of Operation—Pulverized-Fuel-Fired Units

	Black .....Steaming

Notes: When excessive outage has been due to changes in design or other causes not directly chargeable to the unit, the unit has been presented both with and without such periods.

Daily operation logs were printed and furnished to the operators of 234 boilers scattered about the country in 64 stations. An indication of the distribution of the units studied is given in Table 1. A facsimile of the log sheet is published as in Appendix No. 1 to this paper.

Information has been gathered only on boilers operating above 250 lb. per sq. in. gage pressure and containing over 10,000 sq. ft. of heating surface, except that a few with slightly smaller surfaces and operating at very high ratings were included. Although steam reheating boilers were reported on, they have been omitted from this study. It was thought by the authors that they might be included in a future paper supplementing the present one, as a discussion of their particular problems would necessitate more detailed data than are now available.

months. This was also true of certain new installations which were put into operation some time after the investigation started. As the authors did not wish to throw out data indiscriminately, it was decided that the facts shown by a continuous report of ten months should be considered as being sufficiently indicative of actual conditions to warrant the inclusion of such reports in the paper.

These revisions in the original list of units reduced the total to 186 boilers in 50 stations, or an average of slightly over 3 units per station. The largest number from one station was 15, and the smallest, 1.

It must be realized, of course, that two persons or companies may have different opinions with regard to the interpretation of the headings shown on the log. For instance, there may be

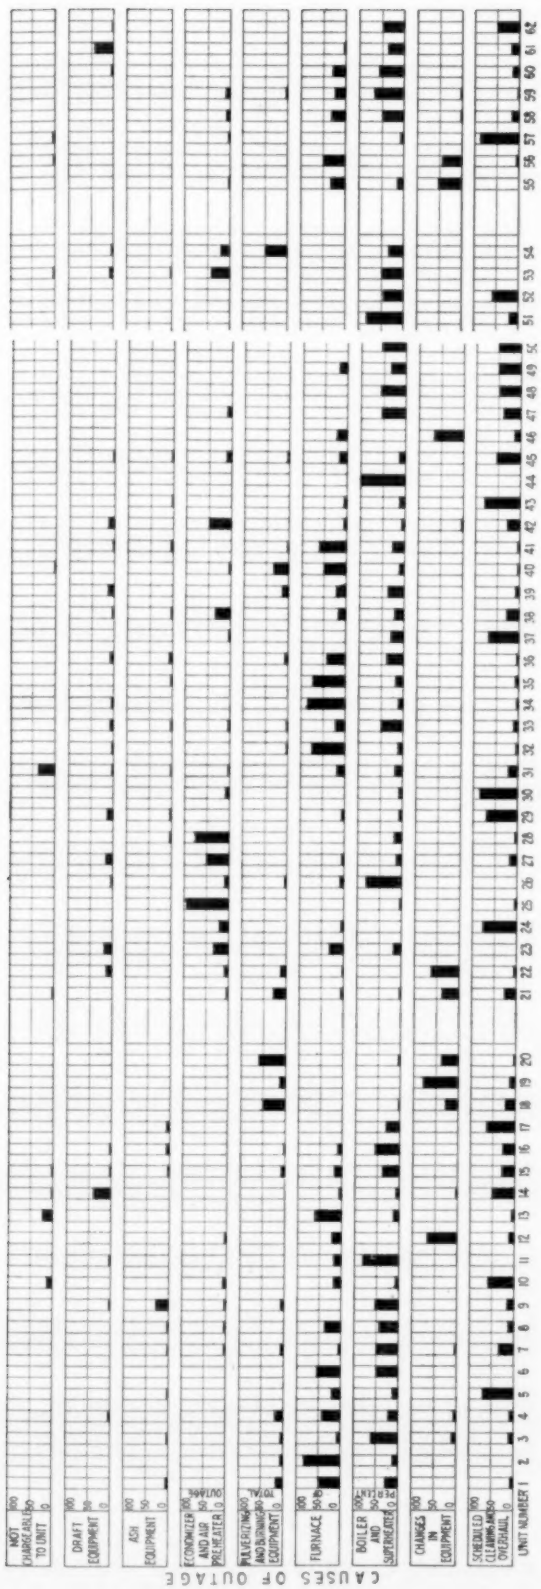

FIG. 6 ANALYSIS OF OUTAGE—PULVERIZED-COAL-FIRED STEAM-GENERATING UNITS

UNITS: 1–20, inc., 400 to 499-lb. class; 21–54, inc., 300 to 399-lb. class; 55–62, inc., 200 to 299-lb. class (Crippled periods classified as to cause and shown as percentages of total outage.)

divided opinion as to when a unit is crippled and when in reserve. The authors have based all their calculations and conclusions on the following definitions which were sent to the field with the log sheets and which the individuals supplying data were requested to observe.

1 A "steaming" unit is one which is passing steam to the line.

2 A "banked" unit is one in which approximate line pressure is maintained with no flow of steam to the line.

3 A "reserve" unit is one which is cold and in which the pressure is near zero, gage, but which may be put on the line in the time it normally takes to lay and light the fire and bring the steam pressure to that of the line.

4 A "crippled" unit is one which is in such a condition that it is incapable of being put on the line within the time it normally takes to bring a boiler from cold to steaming.

In apportioning the reported crippled hours among the various causes, considerable difficulty arose. The authors attempted to get the primary cause of outage in each case and were usually successful in doing so, but many occasions arose in which more than one part of the unit was worked on at one time. For instance, the boiler might be shut down and crippled for repairs to the furnace, but the operators might very naturally take advantage of the opportunity to make extensive repairs to the boiler or stoker. In cases like this the shutdown was charged to the furnace for as long a period as such furnace repairs were reported to extend. Any further crippled time was charged to the secondary job. It was rather difficult to make such distinctions in some cases. However, as the compilation of data was made by a single group of men in the office of the authors, the results should be at least reasonably comparable.

In several cases it was found that a considerable portion of the outage was due to voluntary crippling of the unit for extensive changes in equipment, such as the installation of a new type of wall or burner. In the strictest sense this time should be charged to the unit as outage, because the investment represented in it is idle during such reconstruction and because the actual facts regarding hours available are being determined. Since one might contend, however, that the unit was taken off for reconstruction at a time when it was not needed and could have been kept in service if required, such cases have been shown on the charts both with and without these remodeling periods.

With the modern trend toward complicated design, the old terms, "boiler horsepower" and "per cent of rating" have become less and less descriptive of actual facts. Indeed, there has been a marked tendency throughout the country to discard the old terms and express the performance of steam-generating units in terms of heat delivered per unit of heating surface, furnace volume, or grate surface. The authors, in presenting the results of their study, have used several such methods of expression.

DEFINITIONS AND CONVENTIONS

In addition to the definitions of "Steaming," "Banked," "Reserve," and "Crippled" already given, the following definitions and conventions have been used:

1 The "Total Heat Supplied Water and Steam per Hour" has been calculated as the difference in heat content between economizer inlet and superheater outlet. The result is expressed throughout in thousands of B.t.u. per hour, which unit has been abbreviated as "K.B.t.u. per hour."

2 The "Saturated Heating Surface" has been considered as the surface of the boiling vessel itself as reported by the operator, plus the surface of any hearth screens or water-cooled wall tubes as reported by the operator. Economizer surface is not included in any case.

3 The "Heat Transfer per Square Foot of Saturated Heating Surface per Hour" was obtained by dividing the quantity defined

TABLE 4 INDIVIDUAL HEAT-TRANSFER RATES OF STEAM-GENERATING UNITS

Unit No.	Total steam evaporated, 1000 lb.	Total steaming hours	Average evaporation 1000 lb. per hr.	Saturated steam: Total heat, B.t.u. per lb.	Saturated steam: Heat generated in Boiler, B.t.u. per lb.	Saturated steam: Heat generated in Entire unit, B.t.u. per lb.	Superheated steam: Total heat, B.t.u. per lb.	Superheated steam: Heat generated in Boiler, B.t.u. per lb.	Superheated steam: Heat generated in Entire unit, B.t.u. per lb.	Average evaporation per unit of: Saturated steam surface, lb. per sq. ft. per hr.	Average evaporation per unit of: Furnace volume, lb. per cu ft. per hr.	Average evaporation per unit of: Projected grate area, lb. per sq. ft. per hr.	Average heat output of boiler proper: In saturated steam, K.B.t.u. per sq. ft. sat. surf. per hr.	Average heat output of boiler proper: In superheated steam, K.B.t.u. per sq. ft. sat. surf. per hr.	Average heat output of entire unit represented by: Saturated steam surface, K.B.t.u. per sq. ft. per hr.	Average heat output of entire unit represented by: Superheated steam: Saturated steam surface, K.B.t.u. per sq. ft. per hr.	Average heat output of entire unit represented by: Superheated steam: Furnace volume, K.B.t.u. per cu. ft. per hr.	Average heat output of entire unit represented by: Superheated steam: Projected grate area, K.B.t.u. per per sq. ft. per hr.	Unit No.

TABLE 4 INDIVIDUAL HEAT-TRANSFER RATES OF STEAM-GENERATING UNITS (*Continued from page 277*)

Unit No.	Total steam evaporated, 1000 lb.	Total steaming hours	Average evaporation 1000 lb. per hr.	Saturated steam: Total heat, B.t.u. per lb.	Saturated steam: Heat generated in Boiler, B.t.u. per lb.	Saturated steam: Heat generated in Entire unit, B.t.u. per lb.	Superheated steam: Total heat, B.t.u. per lb.	Superheated steam: Heat generated in Boiler, B.t.u. per lb.	Superheated steam: Heat generated in Entire unit, B.t.u. per lb.	Average evaporation per unit of Saturated steam surface, lb. per sq. ft. per hr.	Average evaporation per unit of Furnace volume, lb. per cu. ft. per hr.	Average evaporation per unit of Projected grate area, lb. per sq. ft. per hr.	Average heat output of boiler proper: In saturated steam, K.B.t.u. per sq. ft. sat. surf. per hr.	Average heat output of boiler proper: In superheated steam, K.B.t.u. per sq. ft. sat. surf. per hr.	Average heat output of entire unit represented by Superheated steam: Saturated steam surface, K.B.t.u. per sq. ft. per hr.	Average heat output of entire unit represented by Superheated steam: Saturated steam surface, K.B.t.u. per sq. ft. per hr.	Average heat output of entire unit represented by Superheated steam: Furnace volume, K.B.t.u. per cu ft. per hr.	Average heat output of entire unit represented by Superheated steam: Projected grate area, K.B.t.u. per sq. ft. per hr.	Unit No.

in (1) by the quantity defined in (2), on the eleventh page. The result is expressed throughout in thousands of B.t.u. per square foot per hour.

4 "Furnace Volume" has been taken as reported by the operator. It is expressed throughout in cubic feet.

5 The "Rate of Heat Transfer per Cubic Foot of Furnace Volume" has been obtained by dividing the quantity defined in (1) above by the quantity defined in (4) above. It is expressed throughout in thousands of B.t.u. transfer per cubic foot of furnace volume per hour. Note particularly that this does not refer to heat liberated within the furnace but to heat absorbed by water and steam.

6 "Grate Area" has been taken as reported by the operator. It is expressed throughout as projected area in square feet.

7 "Availability Factor" has been taken as the ratio between the sum of the hours during which the unit was steaming, banked, or available for service, to the total number of hours in the period.

8 "Use Factor" has been taken as the ratio between the sum of the hours during which the unit was steaming and banked to the total number of hours in the period.

9 In all charts the age of each boiler has been shown by placing upon the bar representing its performance a numeral indicating

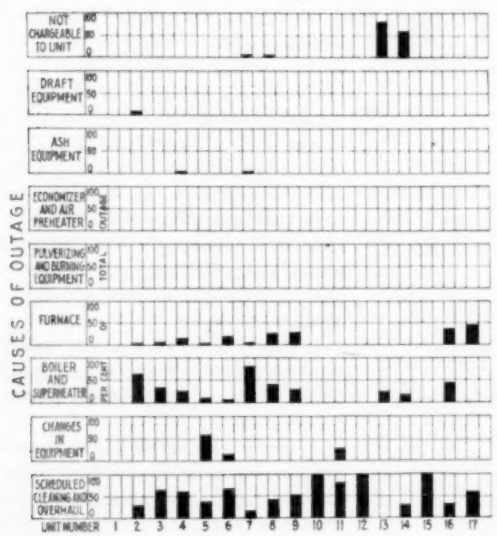

FIG. 7 ANALYSIS OF OUTAGE—OIL- AND GAS-FIRED STEAM-GENERATING UNITS

(Crippled periods classified as to cause and shown as percentages of total outage.)

the year in which it first produced steam. For convenience the two last digits only have been used, thus 1925 is indicated by '25.

10 Each boiler reported on has been given a designating symbol so that it can be identified throughout. The symbol consists of a letter and a numeral. The letter indicates the class of fuel or firing and the numeral indicates the particular boiler in that class. Thus "S-3" means the No. 3 unit in the stoker-fired class. For the sake of simplicity the letter has been omitted in the charts which indicate on their face the class to which they apply.

CONCLUSIONS

The authors feel it necessary to enter here a word of caution. They do not believe it safe to draw final conclusions from a single year's records of such a comparatively small number of boilers, particularly when the numerical values on which the study has been based are subject to the variables arising from different personal factors. The conclusions which follow should therefore be regarded rather as indications, and subject to correction if and when more complete data become available.

Averages of various sorts as obtained from this study are collected in Tables 5 to 8 and Figs. 9 and 10. It may be said, in general, that the results thus far deduced indicate that details of design and construction and operating skill are far more important in obtaining a high availability factor than are such things as rate of output per unit of surface, type of fuel, method of firing, and many of the other factors which have been widely discussed in this connection.

Study of the diagrams and charts indicates that boiler outage is not proportional to severity of use. In fact, it happens that the figures show more outage for many boilers working at a low rate of heat transfer than for those working at comparatively high rates for which data happened to be obtained. This is illustrated in Fig. 9. For easy interpretation imagine the triangle to represent the spreading flame of pulverized fuel, the square to represent the rectangular stoker, and the circle to stand for the initial letter of "other" in "other fuels and methods."

Rather curiously a similar condition is indicated with respect to rate of heat transfer per unit of furnace volume, as shown in Fig. 10.

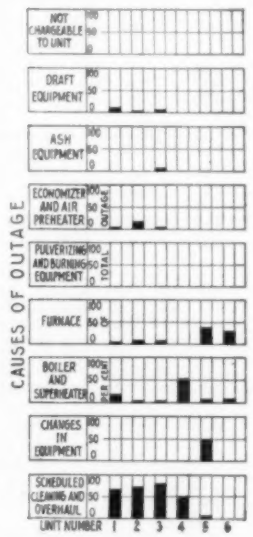

FIG. 8 ANALYSIS OF OUTAGE—MISCELLANEOUS COMBINATIONS

(Crippled periods classified as to cause and shown as percentages of total outage.)

If taken at their face values the results obtained would indicate a slight increase in availability with increasing severity of use. If this be the fact, it is reasonable to suppose that it follows from more careful design and operation in the case of equipment which is driven at the higher rates. The diversity of performances at substantially similar rates of output per unit of surface and per unit of furnace volume would seem to confirm such an interpretation.

Inspection of Figs. 9 and 10 shows plainly that there is no clear evidence of the superiority of either of the recognized methods of firing coal. Points representing stoker firing and pulverized-fuel firing are so well intermingled as to indicate that design and operation are undoubtedly of far more significance with respect to availability than is the method of firing adopted.

An effort was made to obtain further light on this subject by calculating some sort of weighted averages. The results are shown in Table 5 in which the averages are based on the Net Crippled Hours. This expression is intended to cover the author's best estimates of the part of the Total Crippled Hours chargeable to the fuel-burning equipment and furnace. A high degree of precision cannot be claimed because of the unavoidable inaccuracies due to the original reports having been filled out by different individuals with different interpretations, standards, and methods. The averages reported are weighted in the sense that they were derived from the totals of Total Hours Reported and the totals of Net Crippled Hours.

The numerical values obtained appear to indicate highest availability for oil- and gas-fired units, slightly lower availability for pulverized-fuel-fired units, and lowest availability for stoker-fired units. Study of the underlying figures as tabulated indicates that the stoker-fired average is materially lowered by the figure for the 400–499-lb. class. An inspection of the data underlying the tabulated figures shows the low availability of this particular

class to be caused by the inclusion of certain cases which may be properly regarded as abnormal. This is as one would expect, since there is no reason why this particular class should, per se, be so radically different from the other class reported. If the figures for the 400–499-lb. class be omitted, the weighted average availability factor for the stokers becomes 0.846, roughly about as much lower than the value for pulverized-fuel firing as the value for that method is below oil and gas firing. While this is about what one would expect, the authors reiterate that it is not deemed proper to regard such figures as more than indications of probability. The records of availability reported herein for many stoker-fired boilers certainly show that such equipment need not have a low availability factor.

It should be noted that six boilers were reported as using both oil and coal firing. These were omitted when deriving the values given in Table 5.

A study of availability factors of the various pressure classes has been made and the results are assembled in Table 6. There is hardly a significant difference between the various final figures except that the higher availability factor for the lowest pressure class may represent a real difference. At least it is in line with what one might expect.

The situation is quite different with respect to the effect of air preheaters on availability. Results are given in Table 7. It is evident that for all classes tabulated, the air preheater, on the average, decreases the availability factor by about five points. The showing is so consistent that it is believed reasonable to assume that it represents fact. Air-cooled furnace walls were not considered as air preheaters as they seldom raised the temperature of the combustion air above 130 deg. fahr. It should be noted that outages due to things not affected by the use of preheated air were excluded in calculating the factors in Table 7, so that the final values represent the effects of preheated air as accurately as the character of the data permitted.

No conclusions could be drawn with respect to the age of equipment upon availability. When it is realized that most of the units reported on have been placed in service within the past five years, this finding appears reasonable. The older units are not yet old enough to have reached that point where excessive maintenance or even rebuilding is necessary; the younger units are not yet old enough to have passed out of that period during which small changes and modifications are required.

Attempts were made to produce comparison on several other bases with little or no success. The comparatively small number of units and the short operating period covered placed very definite limitations on the possibilities in this respect.

As a matter of interest, Table 8 is included. It shows availability factors for complete turbine units, including auxiliaries. Comparison of the figures in this table with those in the earlier tables will show the degree of real progress made in recent years toward making the availability of steam-generating equipment as high as that of the principal steam-using equipment.

Discussion

J. R. Baker.[4] A paper of this character suggests almost innumerable questions, more perhaps than comments, so that the writer will ask to be pardoned if his remarks are in the form of questions regarding the causes of unavailability rather than an addition to the basic data presented in the paper.

One question that immediately arises is that of effect of use factor upon availability, inasmuch as operating skill is concluded to be a determining factor in obtaining high availability. Some engineers advocate taking a boiler out of service for cleaning and inspection every four to six weeks, while others suggest much longer intervals, even extending to a year. It would be interesting to know if a study of the daily operating logs would indicate which system of operation and preventive maintenance leads to higher availability. In regard to this point also, and with due recognition of the statistical accuracy of the average stated in the paper, it seems that the average availability factors of stoker-fired units and pulverized-fuel-fired units are inverse to the average use factors for the two types of installation—i.e., stokers average 0.769 and pulverized-fuel boilers 0.723, for use factors. Are such figures as significant as the average availability factors?

Again it would seem to be logical in the case of boilers to expect that a factor embracing both severity of use and the use factor, or length of use in the particular period, would be of importance in determining the availability factor.

With regard to Figs. 9 and 10, the conclusion with respect to severity of use does not seem apparent from an inspection, which indicates that availability decreases with increase of severity of use for pulverized-fuel-fired units, in the range between 6 and 12 K.B.t.u. for instance. The plotted points do, however, appear to indicate a slight increase of availability for stokers in Fig. 9, but more nearly a constant or decreasing value in Fig. 10. If, however, note is made that the points at 10 K.B.t.u., which tend to throw the stoker availability upward with severity of use, are derived probably in one station solely, the conclusion regarding stokers would also appear doubtful.

The conclusion with respect to air preheaters is of interest

[4] Operating Engineer, Pennsylvania Water and Power Company, Baltimore, Md. Assoc-Mem. A.S.M.E.

since there has been a discussion recently tending to show that air preheaters deteriorate more rapidly on stoker installations than on pulverized-fuel-fired boilers. Evidently both types of installations are affected equally as to availability. It would be of interest to have further discussion of the causes of outages due to preheaters; i.e., is the trouble in the preheater elements, in the cleaning devices, with associated fans, or with duct work?

With regard to boiler and superheater outages, could an explanation be given to indicate the proportion of outages—as between boiler-water conditions and structural defects, for example?

Another point of interest which may be evident in the detailed figures, but which is not mentioned in the body of the paper, is the effect of boiler size and number of component parts upon availability. There are of course many factors involved, but if there can be any generalization it might be of interest to state whether any difference is apparent.

HENRY KREISINGER.[5] The paper gives us a standard of the availability of steam-generating units for service. We know now that properly installed units can be expected to be available for operation about 85 per cent of the time; that is, approximately six days out of a week.

In Table 2 the last two columns give the heat value of the coal and the kind of stoker or type of firing. It is interesting to note that traveling grates are used with low heat value of fuel and underfeed type of stoker with high heat value coals. That is, traveling-grate stokers are used with high-ash low-grade coals, whereas underfeed stokers are used with high-grade high-carbon Eastern coals. It so happens that the low-grade coals are also free-burning coals and the ash is generally more fusible than the ash of the high-grade Eastern coals. The high-ash coals are therefore more easily burned on the traveling-grate stoker, which does not agitate the fuel bed. The agitation of the fuel bed mixes ash into the burning coal and causes troublesome clinkers.

The high-grade Eastern coals are also coking coals, and therefore cannot be handled satisfactorily on traveling grates. They are burned with much better results on the underfeed stoker, which agitates the fuel bed, thereby breaking the caked-up fuel.

The first 20 stoker-fired units which have been grouped as the highest pressure units are also all fired with traveling grates. Examination of Fig. 5 shows that, if anything, the outage on account of the stoker is less than with the other groups. This is probably one of the reasons why this type of stoker was selected for the low-grade fuels.

Comparison of the last two columns of Table 5 for the stoker-fired and pulverized-coal units shows that the heat value of the coals burned on stokers is generally higher than for the units burning pulverized coal. There are a number of stoker units burning coal exceeding 14,000 B.t.u., and none of them uses coal below 10,000 B.t.u. On the other hand, there are no pulverized-coal units burning coal having heat value as high as 14,000 B.t.u., and there are a number of them burning fuel with heat value of less than 10,000 B.t.u.

Of the total 62 units burning pulverized coal, only 10 units are direct-fired. Apparently there are more units in the central stations fired by the storage system than by the unit system. Although recently a number of central stations were built with the unit system, they have not been operated long enough for reliable records.

In Fig. 9 the pulverized-coal points tend to group themselves toward the side of the higher evaporation per square foot of water-evaporating surface. This is probably due to the fact that pulverized-coal units are more generally equipped with water-cooled furnaces than is the case with stoker-fired units. Water-heating surface placed in the furnace is more effective in evaporating water than heating surface in the bank of tubes of a boiler. This is especially true if the heating surface in the furnace is bare.

In Fig. 10 the pulverized-coal points group themselves toward the side of the lower evaporation per cubic foot of combustion space. This is undoubtedly due to the fact that in the case of pulverized coal all the heat must be liberated in the combustion space, and therefore the volume of the combustion space must be larger than with stoker firing, where only about 40 per cent of the heat is liberated in the combustion space, the other 60 per cent of the heat being liberated in the fuel bed.

BERT HOUGHTON.[6] The paper covering the reliability and availability of steam-generating units is most interesting, and the authors are to be congratulated in compiling so much information within the time they have been engaged in the work. As they have pointed out, no rigid conclusions can be drawn from the data so far assembled, but certainly the writer is as much surprised as they are that increased punishment of the equipment due to high ratings appears from their data to give longer life or greater availability. The writer's experience and observation in the past do not bear this out, and it might be that if instead of average loading one could obtain "load-duration curves," and also a few typical daily cycles of operation to indicate the range and rapidity of change in load and severity of loading, somewhat different conclusions would be reached. Apparently some attempt has been made to evaluate this loading characteristic in the manner of drawing up the diagrams to Fig. 1, but graphically the comparison is not fundamental as certain numerical characteristics at the top of the graph must be visualized at the same time.

The comparison made by the authors on the basis of average evaporation in K.B.t.u. in superheated steam per square foot of saturated surface per hour is apt to mislead, and the comparison should preferably be made on the basis of heat absorbed by the boiler and water screen in K.B.t.u. per hour per square foot of saturated surface. This would make the comparison of all boiler installations uniform and eliminate the heat absorbed in the superheater, economizer, and air preheater, which items should be treated separately. There are a number of boilers in the tabulation with and without economizers and air preheaters and with different amounts of superheating surface.

From the standpoint of the boiler alone without regard to the heat-balance cycle of the station, the work done by the saturated surface has nothing to do with the heat transfer in the economizers or preheaters and superheaters. Therefore the saturated surface cannot be credited with the additional heat transfer of these other surfaces even though there is some interrelation in the final results and temperature of the steam. In order to bring out this point, the writer has taken the No. 54 boiler at Hudson Avenue and figured out the heat transfer; first, with the economizer and superheater; second, without the superheater; and, third, without the economizer and superheater. The results are in K.B.t.u. per hour per square foot of saturated surface. Assuming the last-mentioned method as the basis, there is a difference between the method used in the paper and the method advocated which varies from 19.3 to 29.3 per cent at different ratings. Neglecting the heat absorbed by the superheater only, this difference varies from 4.2 to 11.7 per cent. In other words, where the comparison is being given between installations with and without economizers, air preheaters, and with difference in superheaters, the only basic way to compare

[5] Research Engineer, Combustion Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

[6] Operating Superintendent, Brooklyn Edison Company, Brooklyn, N. Y. Mem. A.S.M.E.

their boiler and furnace performances is on the basis of heat absorbed by their separate surfaces. It is therefore proposed that the definitions on the eleventh page numbered 1 and 3 be changed to suit the scheme of comparison just outlined.

K.B.t.u. in superheated steam per square foot of saturated surface per hour	8.7	8.6	8.5	8.9

Enlarging upon the earlier comment on the detail boiler-operating cycle, the authors have neglected to give the peak performance of the boilers, and this has a marked influence on the outage of stokers and boilers due to slagging, clinkering, possible burning out of tuyères, depreciation of clinker grinder, etc. The writer believes that it would be decidedly worth while to obtain the average sustained steaming capacity of a group of boilers of from four to five hours for the period of at least six consecutive days as a basis for determining what really can be expected of a boiler house. Such work has been carried out at the Hudson Avenue Station, and the results indicate quite a difference between the mathematical determination of the comparison of the capacity of a boiler house from individual boiler test and what may be expected as an average from a group of eight to twenty boilers under normal operating conditions.

In addition to the various items tabulated, it would be most interesting if the authors could obtain the per cent efficiency obtained with the various installations. There might be some connection between outage and efficiency of the boiler house, which relation would be well worth while to analyze.

The writer has compared the fifth row of boilers at the Hudson Avenue Station, which are in the 400-lb. class, with the data submitted in the paper. Fig. 11 is a chart showing this comparison. Due to the fact that the fifth row of boilers was not put in operation until shortly after the initial date for starting the tabulations, these particular boilers were left out of the authors' paper, but this information is furnished as part of the discussion.

EDWARDS E. FISH.[7] The authors are to be commended for the pains which they have taken to gather the unusual statistics on which this paper has been based. The comparisons that have been drawn from them can be of real value. The introduction, development, and growth of the steam turbine and the consequent insistent and increasing demands for more steam at higher temperatures and pressures have been responsible for the very great development in boiler practice, which confessedly has been the follower and not the leader in this development.

The very fact that statistics of this nature could cover only a relatively short period is evidence of the rapidity of the growth.

There has been much to learn by both operators and manufacturers, which knowledge could be attained only by practical experience, and it is largely this experience that guides designers in avoiding objectionable features and evolving correct designs.

In an investigation of this kind there must necessarily be a limit to the minutiae into which it is possible to go, but it would be interesting and instructive to know in detail the reasons for outages. Figs. 6, 7, and 8 divide these causes between the various equipment of a boiler plant, but do not state the character of the troubles. A number of possible causes applying to each of the several subdivisions will suggest themselves to one's mind in thinking it over.

The boiler-operation log shown as Appendix No. 1 does not suggest any causes. It would seem as if such would be of very great service, both to manufacturers of the various types of equipment and to designing engineers, in influencing future design, and that space for their inclusion should be provided in any future effort to gather information.

It would rather naturally be expected that maintenance of the steam-generating end of a power plant would be a greater problem and more expensive than that of the prime mover. However, the statistics in Tables 5 and 8 seem to indicate that, on the average, the percentage of crippled periods of the former is about the same as the latter. This is a tribute to the intelligence and care with which steam-generating units are handled, as well as evidence that manufacturers have profited by experience.

Generally speaking, public utilities have been pioneers in the developments in the power-plant field, and they have primarily been of great service to each other and secondarily to the steam-using industries, of all of which this paper is an illustration.

The writer is especially pleased to note that the authors specifically call attention to the fact that the information presented forms a comparatively narrow premise from which a broad conclusion should not be drawn. There is always the temptation to take figures at their face value without giving due

[7] Vice-President, Heine Boiler Company, New York, N. Y. Mem. A.S.M.E.

consideration to the conditions under which they were gathered and which govern their true significance.

The influence of air preheaters on the availability factor is interesting. One would be inclined to expect less favorable results in connection with stoker-fired plants than in the case of pulverized fuel or oil and gas, but the differences as shown by the statistics are not so very different, although the indications are that it is less with pulverized fuel than with the others.

Investigations of this sort supply one more item by which the judgment of power-plant designers may to some extent be guided.

It is to be hoped that either the authors of this paper or someone else will in due time extend the investigation.

JOHN H. LAWRENCE.[8] The Central Station Committee of the Power Division is to be complimented for initiating such an important study as that covered by this paper, and the authors are to be congratulated for compiling such an enormous amount of information in such a way that it is readily interpreted. It is a very difficult job to induce various companies and engineers to furnish information as it is requested, but in this case the authors have apparently secured very good results.

It is to be regretted that this study was not initiated some years ago, at least before the development of the water-cooled furnace. There is no doubt that the water-cooled furnace has materially increased the availability factor of boiler units, as the most serious cause of outages in the average plant was maintenance on the furnace brickwork. This brickwork maintenance in some plants ran into startling figures.

The water-cooled furnace has reduced boiler outage, due to wall maintenance, almost to a negligible amount, especially in the case of pulverized-fuel boilers.

It may be of interest to know that the older boilers in the East River Station operated at 400 per cent of rating or over for a period of one year up to the time that the new 800,000-lb. boilers were placed in operation. Every one of these boilers was available every working day on the peak, and the only trouble on the walls was the replacement of one sidewall tube, which was due to a condition which can be eliminated in the future.

One boiler in this station has been available every day for the last year and eight months. These boilers are entirely water cooled, with the exception of a small amount of refractory around the headers and air lanes.

When the late Thomas E. Murray suggested 100 per cent water-cooled surfaces in these boilers, the idea was frowned upon by almost every one, as it was thought that an all-water-cooled furnace would materially affect the efficiency of the boilers. However, he took the position that this might possibly occur, but if it did the remedy should not be through covering the water-wall surface, but by improving the design of pulverized-fuel burners.

The efficiency was low on starting these boilers, but the burners were improved, and the result has been that these boilers compare very favorably in efficiency with any other boilers operated under the same conditions.

From the experience at East River Station, the writer would say that the statement of the authors on the second page no longer holds true, as the availability factor of a boiler unit so designed should be well over 90 per cent. This statement reads as follows:

> It is the hope of every central-station designer and operator that some day the steam-generating equipment may be brought to such a stage of perfection of design and construction that, when properly operated, it will have the same degree of availability for service as characterizes the modern steam turbine attached generator and subsidiary or auxiliary equipment.

The National Electric Light Association Prime Movers Report for 1926 and 1927 shows a weighted availability factor for units in service from one to ten years of 86 per cent. This figure is even lower than the availability factor reported by all the pulverized-fuel units which are given in this paper.

It is safe to say that the modern boiler unit on an average has an availability factor considerably in excess of the turbine.

The authors comment concerning the availability of boilers at high ratings being no lower than at low ratings. In fact, if anything, the availability is slightly higher at high ratings. This is contrary to the experience of the time before the introduction of the water walls. At that time it was felt that boilers could not be operated at high ratings without causing considerable punishment to the walls. There is no doubt that high rating on a refractory furnace is very injurious, but there were no grounds for the argument that the boiler itself might be damaged. Recent practice has shown that the boiler is capable of withstanding almost any load to which it might be subjected—at least so far as it has been possible to operate boilers up to the present time.

Table 6 shows the comparison of availability factors of different pressure classes. Perhaps the evidence is not sufficiently complete so that it is conclusive. However, if it justifiably indicates that availability factor decreases with increase of pressure, the statements which have been made concerning high-pressure plants are not in accord with the facts presented in this paper.

The margin of gain in high pressures is so slight that if the availability factor does decrease with pressure, as shown, the probable savings which have been estimated will be wiped out by the extra expense due to more equipment being necessary to carry the load on account of decreased availability.

NEVIN E. FUNK.[9] The efforts that the authors have spent in compiling the comparative data on the availability of boiler units are to be very much commended by the engineers of all industries whose work involves them in boiler-plant design or operation. To the writer's knowledge this is the first time comparative data of this kind for boiler units have been made available to the industry.

The writer desires to emphasize the fact, which the authors have brought out in their paper, that these data should be used with a great deal of caution in making comparisons. This cautionary advice is no reflection upon the data presented by the authors, but is merely a warning based on personal experience in gathering data from many sources.

No matter now concisely or how carefully methods of collecting data are prepared, they are always subject to misinterpretation by those responsible for collecting the data at their source. This misinterpretation may be due to misunderstanding the intent of the person requesting the information or may be due to differences of opinion as to the location of the dividing line between various elements of the data sought.

As more concrete examples of this thought in which differences of interpretation might easily exist, the writer believes it is not out of place to point out that even what might appear as so simple a thing as determining the actual steaming and banking periods of boilers in the field is subject to error, for unless the pressure of an individual boiler is definitely below the line pressure, it cannot with surety be determined that this boiler is not steaming. No instruments have yet been evolved which are delicate enough to measure extremely low steam outputs if they are capable of measuring high steam outputs. The concrete

[8] Vice-President and Engineering Manager, Thomas E. Murray, Inc., New York, N. Y. Mem. A.S.M.E.

[9] Assistant Chief Engineer, Philadelphia Electric Company Philadelphia, Pa. Mem. A.S.M.E.

proof of this is the fact that it is possible to carry a 10,000-kw. output on a station with a 180,000-kw. capacity without any apparent output from any of the boilers shown on the steam-flow meters and with no draft under the fires.

And again, it is quite possible when a boiler is in reserve that the operating force may elect to do some repair work on the unit which actually puts it out of service, but which repair work could be at least temporarily completed by the time that the fire in the furnace had been built up to a point where the boiler could be utilized. This boiler would not be classified as crippled.

These examples indicate that even though the authors have made very definite demarcations between the four classes of conditions of boiler operations, nevertheless the men in the field who are making the subdivision of time of these various classes of service might very readily err on one or the other side of a correct line, which in the total might change the results obtained materially.

Quite obviously, boilers S 29 to 35, inclusive, have such an extremely low period of crippled time that it seems almost impossible to believe that the data submitted on these units can possibly conform to that submitted on the remaining boiler units.

This type of inconsistency always exists in collecting data of this kind, and it is only after data have been collected several years from the same units that these inconsistencies can gradually be eliminated due to the bulk of the data that are obtained.

This, then, is another reason for caution in using the statistics presented; that is, they are not of sufficient duration to permit the authors to eliminate obvious inconsistencies in the reports of some or all of the field forces. Furthermore, the short period of time over which these data have been compiled does not allow for the variation in maintenance that takes place from year to year, and therefore may not give the possible trend in the performance of the units listed.

The authors have shown in Table 2 a comparison of the various availability factors, and it is interesting to note from these data the definite increase in percentage of pulverized-fuel units above stoker-fired units and the corresponding increase of oil- and gas-fired units over pulverized-fuel-fired units. However, the weighted average age of the stoker-fired units is greater than that of the pulverized-coal-fired units or the oil-fired units. This may or may not have some effect on the factors involved, but is one of the reasons why the relative difference in availability factors should not be used with too greater certainty.

Figs. 5 and 6 in the authors' paper indicate that the furnaces of the stoker-fired units seem to be less responsible for outage of the boiler than the furnaces of the powdered-coal-served units.

This, however, is not indicative of the possibilities of more furnace trouble with powdered coal, since the powdered-coal boiler appears on the average to have less crippled time than the stoker-fired boilers. This in itself would have a tendency to increase the percentage of outage time due to the furnace if the furnace troubles were of the same order in actual hours outage as the stoker furnaces.

The writer is sorry that the authors did not make a comparison of the subdivision of the percentage outage as a function of the total hours included in the period under observation rather than a percentage of the crippled period, since this would give a more ready comparison between the different types of firing so far as the effect on availability is concerned.

It is interesting to note the relative necessity for correction in the initial design of the different type units and the effect of this on the crippled time of the particular units involved. This can be given as follows:

Type of firing	Per cent of total units involved	Average per cent increase of crippled time due to design changes on units involved
Stokers	0	0
Pulverized fuel	11.3	70
Oil and gas	11.8	139

The foregoing comparison is subject to the same limitations noted by the writer in regard to some of the comparisons made by the authors.

The authors have presented two extremely interesting curves in Figs. 9 and 10, which show that crippled time is much more a function of design or careful operation than of rate of combustion or type of firing equipment. Of course, data for several additional years may indicate a very definite trend for each type of firing, and it is to be hoped that it is not asking too much of the authors to continue the good work they have started.

These data extended over a longer period will be extremely valuable.

Ollison Craig.[10] At the conclusion of this paper are two figures; one, Fig. 9, shows boiler availability plotted against average evaporation per unit of saturated surface per hour; and the other, Fig. 10, shows boiler availability plotted against evaporation per unit of furnace volume per hour. Triangles represent data from powdered-fuel-fired units, squares represent data from stoker-fired units, and circles represent data from units fired by other means. Abscissae used in either case are a function of coal-burning rates. Inspection of the scattered points indicates that increase of evaporation does not decrease availability, but might even be considered to increase availability, as pointed out by the authors. It might be expected that, if availability was affected by method of firing, the difference would most probably be found in outage on account of firing equipment or furnace. In the case of stoker firing certain experiences bear out the conclusion quite definitely. This writer recalls one case in which two stokers of same type and size, set alike, under the same size and kind of boilers, were fired for a period of one week, one stoker being carried on bank and the other operated to limit of capacity. The stoker which was pushed to limit of capacity suffered no damage, while the banked stoker required renewal of a number of parts due to burns.

If coal is burned on a stoker at a greater rate, an average thicker fuel bed will usually be maintained, providing more protection to the iron parts from furnace radiation; and more air and raw coal will carry more heat away from the iron. If the fuel-burning rate is low, fire can burn down into the fuel bed at certain points and come in contact with the iron.

In the case of powdered-coal firing an increase of availability could be shown due to the fact that installations operating at the greater rates of heat absorption per square foot of saturated surfaces are more probably equipped with water walls, and outage due to furnace repairs is reduced. A study of data presented, in the case of powdered-coal firing, indicates furnace outage to be about 24 per cent of total outage with refractory walls and about 15 per cent with water-cooled walls.

This writer wishes to raise a point in connection with Figs. 9 and 10. Fig. 9 compares powdered-coal firing and stoker firing on the same basis, but Fig. 10 does not. Heat absorbed by steam may be considered approximately proportional to heat released in the furnace. So, heat released in the furnace could have been used as abscissae in Fig. 10, and the relative position of the points would remain about the same. However, it must be remembered that in the case of powdered-coal firing the heat released in the furnace is the result of burning the coal, both solids

[10] Consulting Engineer, Riley Stoker Corporation, Worcester, Mass. Mem. A.S.M.E.

and gases, as the coal passes through the furnace space, while in the case of stoker firing the greater portion of the fuel is burned on a practically stationary fuel bed, and the heat released in the furnace space by burning combustible material in this space represents the smaller portion of the total heat in the coal burned. The two conditions are in nowise comparable.

Table 5 indicates that of the three methods of firing, stoker-fired installations have on the average the greatest outage, powdered-coal firing is next, and oil and gas firing the smallest outage. A knowledge of the reasons would be interesting. It might be considered as being largely due to the firing equipment and the effect on the furnaces. Averages taken from data in Table 3 indicate that, in the case of stoker installations, the stokers and furnaces are responsible for 27.5 per cent of the outage time, 15 per cent being due to the furnaces and 12.5 per cent due to the stokers. Also, in those installations having refractory walls, furnaces are the cause of 16.2 per cent of the outage, while on the case of water-wall installations this figure becomes 10.4 per cent.

In the case of powdered-coal installations, powdered-coal equipment and furnaces are responsible for 24.8 per cent of the outage time, this being divided 19.2 per cent for the furnaces and 5.6 per cent for the powdered-coal equipment. Outage due to furnaces is 24.1 per cent in the case of refractory walls and 14.9 per cent in the case of water walls.

The data would then indicate that powdered-coal equipment is more dependable than stoker equipment, as indicated by comparison of the outage percentages of 5.6 and 12.5, but that the percentages 19.2 and 15 indicate that there is room for development along the lines of furnace design in the case of powdered-coal firing. This development will probably occur through better designs of water walls for high capacity units and application of better knowledge of furnace design, together with better designs of burners in the case of refractory walls.

A decided difference in availability is shown with and without air preheaters. A knowledge of the reason would be interesting. Is it due to repairs required to preheaters? Does any type of preheater cause less outage than others? Is the outage due to the effect of hot air on other parts of the equipment, and if so, how does it vary with the different methods of firing?

J. G. Worker.[11] There have been read two very interesting papers. Mr. Clark tells the best kind of a boiler plant that can be obtained and the amount of money that can be invested wisely, and Messrs. Hirshfeld and Moran show how easy it is, after spending this money, through detailed weaknesses and cripples to destroy the proper return on the investment.

Both papers state that we are in the midst of a business consideration of the utility of boiler units, and the information and data in these papers should not, as the authors caution, be used to draw final conclusions, but rather to help correct weaknesses and give more skilled attention to those elements of design that affect reliability.

Particularly interesting are the stoker data in these papers. A few years ago stoker and boiler units were of small size as compared to the modern units of today. More coal per foot of furnace width is being fed than ever before, which means the generating of more steam per foot of furnace width.

It will be noted from Table 9 that the newer stations now under construction, such as Delray No. 3 of the Detroit Edison Company and the Bewag Station of Berlin, Germany, are designed to give very high steam outputs per foot of furnace width.

Control of Stoker Fuel Beds

The control of the fuel bed, and especially the big fuel beds required for large steam units, introduces forces that must be opposed by the mechanical design of the fuel-feeding structure of a stoker mechanism. When stokers were only eight or ten feet long, as of a few years ago, the fuel-feeding mechanism of older stokers was ample to withstand any forces introduced in handling the fuel to the grates. With larger stokers a completely new development—although following the same principle, but really a new departure in design—has taken place, as shown in

TABLE 9

Station	Pounds of steam per hour per foot of furnace width, stoker-fired plants		Pounds of steam per square foot of furnace area, stoker-fired plants	
	Maximum	Continuous	Maximum	Continuous
Delray No. 3	17,200	12,500	735	530
Bewag	17,000	11,400	835	555
Beacon Street	16,700	6,600	640	250
Hudson Avenue	15,200	9,000	770	450

Richmond	7,000	4,200	535	330

Fig. 12. An example of how the design of different parts has changed, due to this influence of controlling all parts of a big fuel bed, is shown in Fig. 13. This shows how much more

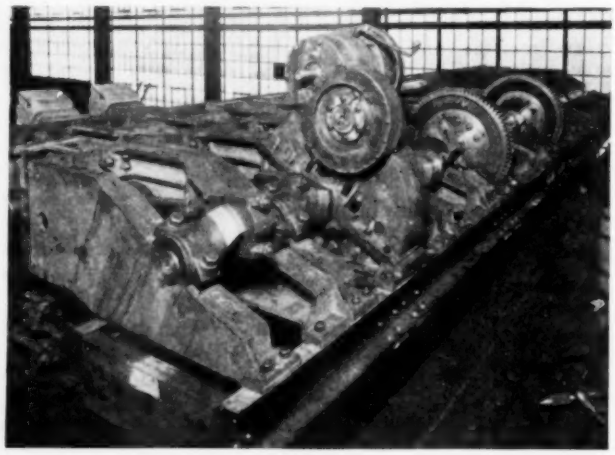

Fig. 12

strength is being put into the high-capacity stoker than into the smaller stoker of a few years ago.

Starting Up Boiler Units

A boiler unit today has many new things attached to it; and it has been found in the starting of new plants that one thing or other happens, making it necessary to take the boiler unit out of service until changes are made. It seems that we can help this situation by extending the same engineering skill in the starting up of plants as has been manifested in the creation of its design.

There is no question that the availability factor of boiler units has been considerably less in the starting of new plants than after that period of changes and modification. We therefore can look for a vast improvement in this particular situation if more thought and effort are put into the unit in the beginning.

It is interesting in reading a foreign contract, covering boiler and stoker units, to find that it not only included specifications of design, but also specifications covering the method by which the boilers and stokers would be put in operation. In part the specifications covered the following:

In a modern boiler setting, mechanical defects may show up in starting, such as defective high-pressure fittings, boiler tubes,

[11] General Sales Manager, American Engineering Company, Philadelphia, Pa. Mem. A.S.M.E.

superheater tubes, water walls, stoker parts, etc., so that by a process of elimination all elements will be tried out. It is proposed that in starting no combustion problems will be involved. A very good grade of coal will be selected of which its action in firing is well known, and even though it is a better grade of coal than will ultimately be used at the plant, a knowledge

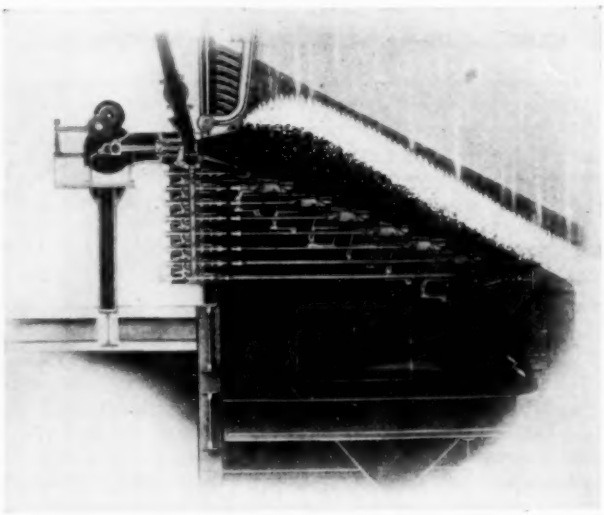

FIG. 13

of this good coal and its use will assure on the start no problems in its burning. If a plant is designed for high preheat, the start will be on cold air planned for a definite period of operation; then a small amount of preheated air will be run for a certain established period. At the start the unit will not be put to test for

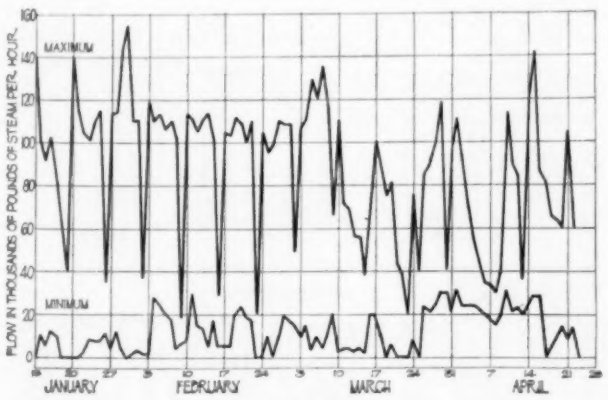

FIG. 14

its ultimate capacity, but rather a normal rating will be rigorously adhered to until it is definitely established that all mechanical parts have stood the test of normal rating. Then the unit will be gradually tested for high capacity. After the unit has stood the test for all mechanical defects, the burning of the various grades of coal that normally will be used at the plant will be started, with the assurance that no mechanical interruptions will interfere with the problems of burning the coal to the best advantage both as to efficiency and rate of burning.

EXAMPLE OF USE FACTOR

The authors make this statement: "The records of availability reported herein for many stoker-fired plants certainly show that such equipment need not have a low availability factor." The writer would like to cite an actual example to confirm this statement of a carefully planned boiler unit that was started and held on the line about four months. This was a modern 45 underfeed stoker applied to a 1000-hp. boiler. It was the one dependable boiler unit in a heating plant. It was absolutely necessary that the unit stay on the line, and it did for about four months. The maximum and minimum steam

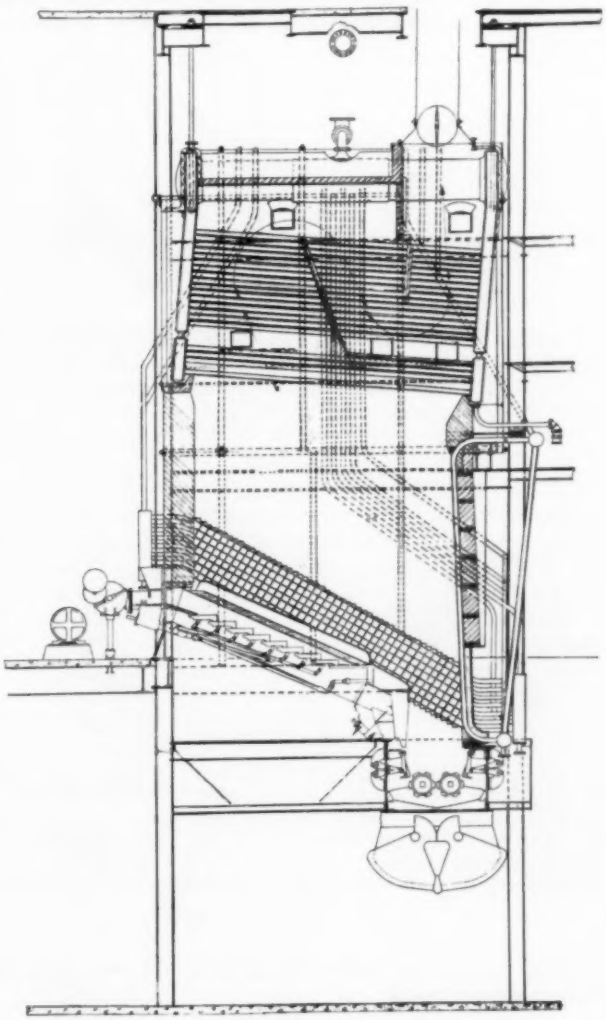

FIG. 15

outputs during this period are shown in Fig. 14. The furnace is equipped with partial water cooling on the two side walls and rear walls, as shown in Fig. 15.

After the unit was taken off the line, a careful inspection was made, and the indications were that the unit could have run much longer, as there were no apparent immediate repairs required for the stoker, water wall, or boiler.

WATER-COOLED WALLS

It is noticed in the paper that, out of 101 stoker-fired plants reported, only 24 plants have water-cooled walls. Of the 62 pulverized-fuel plants reported, 34 have water-cooled walls. In other words, 55 per cent of the pulverized-fuel furnaces are water cooled against 25 per cent of the stoker-fired furnaces.

Many of the new stoker-fired plants now going in have water-cooled furnaces, so that one can look for an improvement in the availability of stoker-fired furnaces in so far as the furnace outages are concerned, especially when reports come in to show at least 50 to 75 per cent water-cooled furnaces for stoker-fired plants.

Even older plants have already sensed the value of the modern furnace construction and are shaping their expansions to take advantage of these new elements by removing old stokers and putting in modern water-cooled walls and modern and larger stokers. It is being shown that not only higher availability

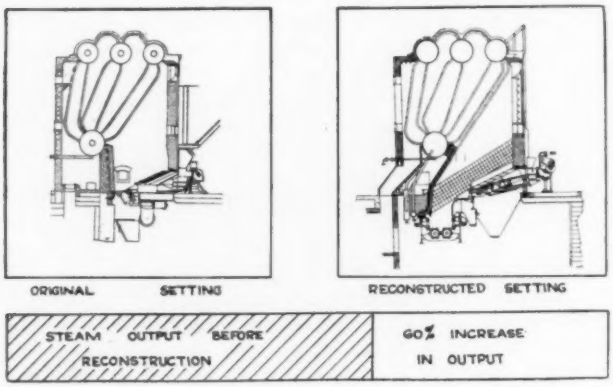

Fig. 16

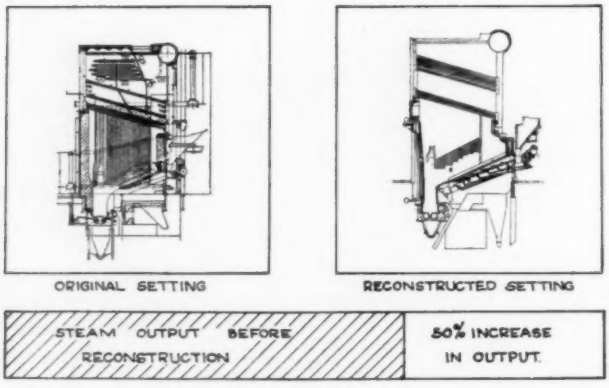

Fig. 17

is being obtained but higher thermal efficiency and greatly increased steam outputs.

Two Plants Typical of the Future

The writer would like to cite one or two important modern jobs that are typical of what we may look forward to as a means of increasing the availability factor of stoker-fired plants.

Plant "A," a steel plant remodeled, had three boilers equipped with old dump-grate-type underfeed stokers. With the old plant, with the three boilers in operation, it was possible to obtain continuously 61,500 lb. of steam per hour, and on a peak 81,600 lb. of steam per hour. It was decided to remodel the boiler plant and revamp the old stokers, changing them to a crusher-type stoker and with increased grate surface. The setting before and after remodeling is shown in Fig. 16. The new boilers are designed to give continuously about 100,000 lb. of steam per hour, and on a peak 130,500 lb. of steam per hour. This will give a continuous increase of about 30,000 lb. of steam per hour, and a peak increase of about 50,000 lb. of steam per hour.

The complete cost of revamping the old stoker-fired boilers was about $65,000. This included new stokers, side and rear water walls, brickwork, excavation, complete erection, and everything ready for steam generation. On this basis of cost the additional steam figures $2.17 per pound of steam continuously and $1.30 per pound of steam for peak loads.

Plant "B," a central-station plant remodeled, is an installation

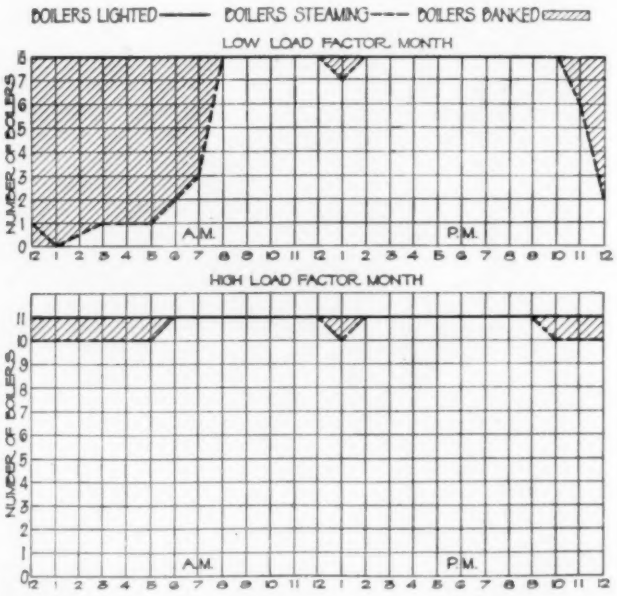

Fig. 18

(Legends: Heavy solid line, boilers lighted; heavy broken line, boilers steaming; single cross-hatching, boilers banked.)

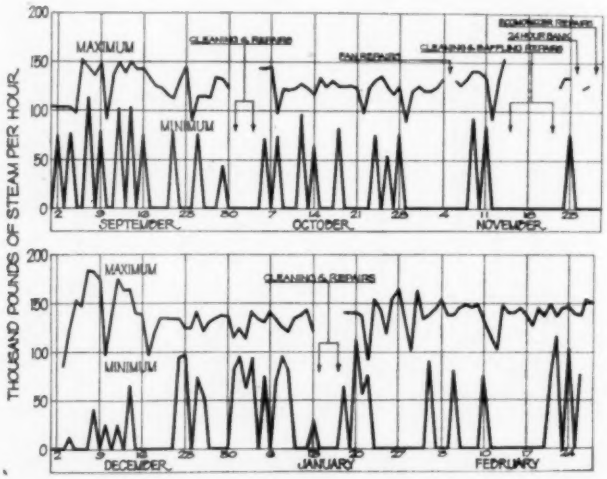

Fig. 19

having 14-retort 33-tuyère underfeed stokers installed under 1710-hp. boilers. One of the settings is being remodeled by removing the 33-tuyère stoker and installing a 53-tuyère stoker, as shown in Fig. 17. The 53-tuyère stoker will have a grate surface of 493-sq. ft. and additional grate area of 115 sq. ft. With the old installation, 200,000 lb. of steam per hour was obtained by burning 78 lb. of coal per square foot of grate surface per hour. With the remodeled setting an evaporation of 300,000 lb. continuously per hour will be obtained at the rate of 72 lb. of coal

per square foot per hour. On a basis of burning 78 lb. of coal per square foot per hour, the new evaporation will be 330,000 lb. of steam per hour. In the new stoker all of the furnace changes will cost approximately $150,000. Taking the 330,000 lb. of steam that the remodeled setting will give over the old 200,000 lb. of steam, the cost of this remodeling job will amount to $1.15 per pound of steam increase.

Banking of Stoker-Fired Boilers

The ability to bank an equipment over long periods with a minimum fuel loss, the authors show, has a marked effect on the "availability factor."

If it is possible to have an active fire on the fuel bed ready to respond to any operating condition, in a great number of plants this has considerably more of a value as to its availability than if the boiler is out.

The large Richmond Station of the Philadelphia Electric Company has recently had an opportunity to gage the full value of this factor, because it had been necessary to operate with a very high load factor while at other times it was necessary to operate with a low load factor. Fig. 18 is a typical boiler schedule for both the high- and low-load factor periods.

Fig. 19 shows a steam output chart for one of the typical boilers of the plant.

Some very interesting figures covering the operation of the Richmond Station show a very high efficiency for both the low- and high-load factor periods.

Results of Richmond Station

Preheated Plants. The authors have given a comparison of the availability factors for units having air preheaters and those operating on cold air.

The operation of the Beacon Street Plant of the Detroit Edison Company is interesting because these units do not have any so-called heat-recovery devices. It has no economizers, no preheaters, no water walls. A typical output chart is shown in Fig. 20. It will be noted that over 350,000 lb. of steam is taken out of the unit on peaks.

The data in Fig. 11 were taken from the operating records kept at the Beacon Street Plant. They illustrate the characteristic operation of the plant.

The boiler efficiencies shown in Table 10 are those derived from the weekly computation and are based on the amount of make-up water used as determined by an accurately calibrated V-notch meter.

The writer has the history of the boiler operation of this plant from the time it started on September 27, 1928, up to the end of the heating season, May 31, 1929. A total of seven days of boiler outage may be charged to stoker repairs during the whole season of approximately 720 boiler days. This amounts to about 0.97 per cent.

This record and similar analyses indicated by the authors show the suprisingly large number of elements affecting boiler outage. Engineers may well devote a great deal of study to the causes of these outages and means for reducing them.

TABLE 10

NOTE: From 15 to 20 per cent of all the steam leaving the boilers is used for feedwater heating. The balance is the steam output.

Dr. D. S. Jacobus.[12] These papers[13] are of great value in recording progress in the improvement of steam-generating

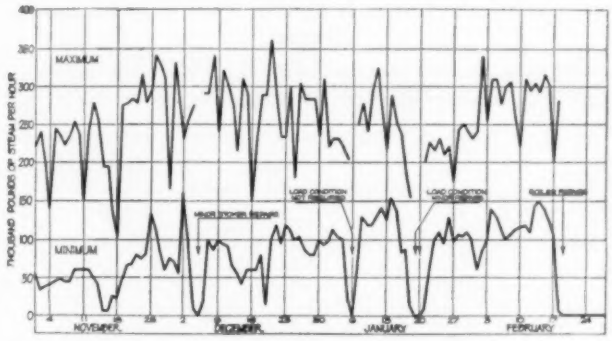

Fig. 20

plants. The trend, as brought out in the papers, has been toward increased size and output, improved firing methods, improved arrangement of the boiler and heating surfaces, improved auxiliary equipment, and in employing greater operating skill.

The higher steam pressures and temperatures which are in use today, and the higher rates of fuel burning and consequent increase in the rates of evaporation, demand a correspondingly higher grade of workmanship and materials and have taken the construction of a steam-generating equipment out of the old-time boiler shop and put it into a high-grade machine shop. All this has resulted in securing a higher reliability as well as an increase in the thermal efficiency of the plant as a whole. It is gratifying to note that the availability for service of large boiler units has become as high as that of the turbine units and that the added efficiency has not been purchased by a counterbalancing increase of investment, so that the advance has been made in an economic sense as well as a purely technical one. This is the result of developments which have been made step by step in reaching the degree of perfection obtained today, and it represents progress made through the cooperation of many men and minds.

The results secured are of interest to all and deserve a most careful study. The continuation of the investigation should have most hearty support.

Authors' Closure

Mr. Baker's mention of the apparent effect of use on availability suggests the presentation of the data as shown in Fig. 21. Use factors are plotted against availability factors without allowance for severity of use. It is interesting to note how closely many of the units hug the limiting diagonal. The predominance of points representing stoker-fired units near the diagonal may possibly be explained by variation in interpretation of definitions. A stoker-fired boiler on bank would undoubtedly be interpreted as "in use," whereas a pulverized-fuel-fired or oil-fired boiler might equally well be interpreted as "in reserve."

Another point raised by Mr. Baker is dealt with in Fig. 22, which attempts to show the effect of complica-

[12] Advisory Engineer, Babcock & Wilcox Company, New York, N. Y. Mem. A.S.M.E.

[13] The discussion also includes the paper by Frank S. Clark on "Effect of Large Boilers at High Capacities on Operating Characteristics and Investment in Boiler Plant."

tion in design on availability. Units having unprotected walls are compared with others which have air or water cooling. The latter class ranges from complete protection to only partial protection of vulnerable spots. Each class is divided into groups which vary from the simple boiler to the more elaborate combination of boiler, economizer, and air preheater.

Improvement in Design Is Keeping Pace With Increased Driving

At first glance the chart seems to favor the more simple designs with unprotected walls, although the difference is very

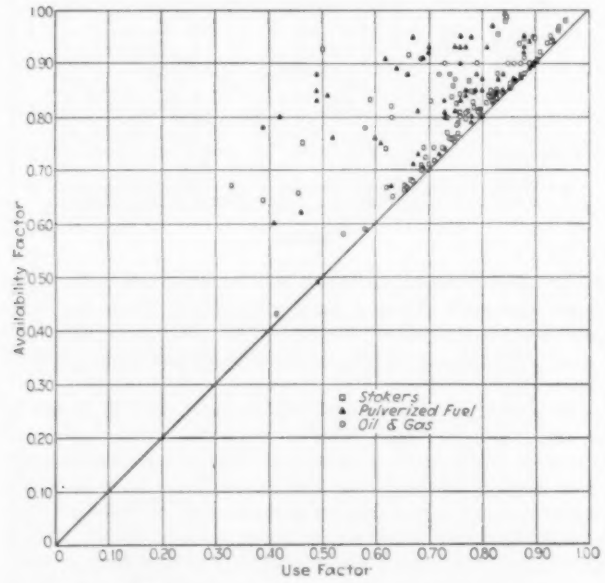

Fig. 21 Effect of Use Factor on Availability

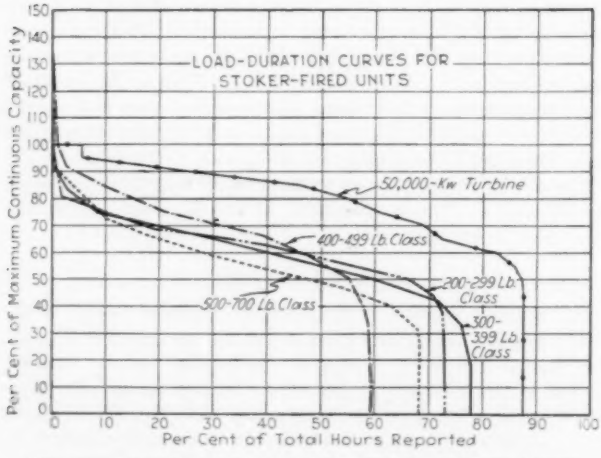

Fig. 23 Load-Duration Curves for Stoker-Fired Units

slight. It seems probable that if severity of use could be taken into consideration the more complicated designs would be shown to be the better from the standpoint of use of investment. At any rate improvement in design seems to be keeping pace with increased driving.

At Mr. Houghton's suggestion the authors have constructed load-duration curves as shown in Figs. 23 and 24, for the various classes of steam-generating units. These are composite curves and represent averages of each class and not extremes. The turbine curve represents the average load duration of the machines in one typical high-load factor, but not base-load station. The maximum continuous capacity for each boiler as used in plotting these curves was reported by the station operators.

Mr. Funk suggests that, if the causes of outage were expressed as percentages of the total time reported, the troubles caused by the various parts of the units would be more readily com-

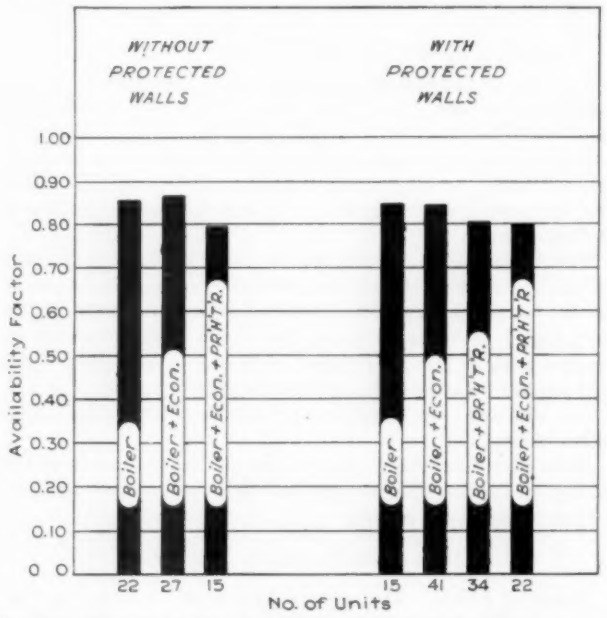

Fig. 22 Effect of Complication of Design on Availability

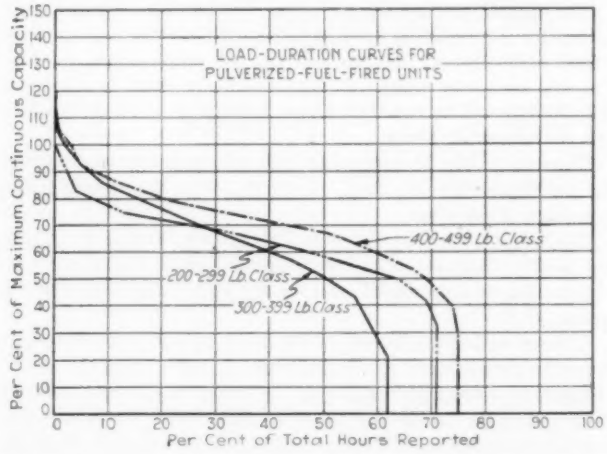

Fig. 24 Load-Duration Curves for Pulverized-Fuel-Fired Units

parable. This change has been made and is presented in Table 11.

The averages by classes are given in Table 12 so as to make them readily comparable.

Impossible to Determine Actual Heat Released

Mr. Craig calls the attention of the authors to the unit used as the abscissa in Fig. 10, pointing out that, if rates of driving with respect to furnace volume are to be compared, the unit used should be based on the heat released in the furnace. This is perfectly true, and such a unit would have been used had the necessary information been available. The data, as collected, did not include quantities of coal burned or efficiencies, so it is impossible to determine the actual heat released in each fur-

TABLE 11 ANALYSIS OF TIME UTILIZATION

OUTAGES CLASSIFIED AS TO CAUSE; EXPRESSED AS PERCENTAGE OF TOTAL PERIOD

Unit number	Scheduled cleaning and overhaul	Changes in equipment	Boiler and superheater	Furnace	Stoker	Pulverizing equipment, burners	Economizers and air preheaters	Ash equipment	Draft equipment	Not chargeable to unit	Total outage
Stoker-Fired Units, 500 to 700 Lb. per Sq. In. Pressure

nace. It was therefore necessary to use a unit which represents only approximately that which would have been used if available.

The authors regret that insufficiency of data prevents them from going further into the various lines of study suggested by other discussers. The discussion as a whole has been very gratifying, and it has shown an interest in the study sufficiently great to warrant its continuation. The authors have therefore resumed the collection of boiler-outage data. They hope to be able to continue for at least two more years, and have added more power stations to the list, including several industrial plants.

With this increase in scope, and profiting by the experiences of the first year and the suggestions made in the discussion, it is believed that the results will become increasingly conclusive.

TABLE 12 OUTAGES CLASSIFIED AS TO CAUSE AND METHOD OF FIRING

(Average Outages Expressed as Percentages of Total Period)

	Stokers	Pulverized coal	Oil and gas
Scheduled cleaning	7.8	3.6	6.9

Draft equipment	0.7	1.3	0.6
Not chargeable to unit	1.1	0.8	14.0

FSP-52-35

Working Stresses for Steel at High Temperatures

By D. S. JACOBUS,[1] NEW YORK, N. Y.

Certain of the published results for the stress to produce creep at higher temperatures have led to apprehension in the employment of stresses that have been used, and it is the object of the paper to dispel such apprehension for the particular stresses which are discussed.

The results secured in practical experience are used for setting the maximum working stresses for drums and superheater headers up to temperatures of 800 deg. fahr., and for temperatures above 800 deg. fahr., the working stresses are scaled down in proportion to the falling off of the stresses that produce creep. The first curve of creep stresses published by Mr. H. J. French of the Bureau of Standards was used, and the working stresses for a given temperature are taken at 2/3 the creep stress. The effect on the stress of piercing a boiler shell with holes and of transmitting heat through the shell is discussed, as well as the tendency toward equalization of stress through extension of the most-strained fiber. The tendency of the creep to equalize the stresses is also brought out.

The method of extrapolation used by different authorities is discussed, and the conclusion is reached that more exact results are obtained by using the method employed by Prof. F. H. Norton in his book on the "Creep of Steel at High Temperatures" than by some other methods.

THE safe working stresses for the shells of boilers and pressure vessels have been determined to a greater extent by experience in the use of such vessels under actual operating conditions than by any theoretical rules. These stresses are ordinarily based on the average stress in the ligaments between tube holes or the like. This is an approximate method. On the one hand the stresses in the metal at the sides of a hole in a drum which is stressed within its elastic limit may be twice or over the average stress in the ligaments or in the solid plate where a single hole is placed in a seamless shell. On the other hand the ductility of the steel causes the stresses to be different after a drum is placed in service than when subjected to the initial pressure, the general effect being to cause the stresses to be more uniform under working conditions than on the initial application of pressure.

That the service conditions have much to do with the pressure at which a vessel can be safely operated may be seen on considering a seamless cylindrical drum having a hole drilled in its shell. If such a drum is subjected to a gradually increasing pressure, the stress at the sides of the hole of, say, twice the average stress in the plate will cause the stress in the metal near the hole to exceed the elastic limit when a certain pressure is reached. On increasing the pressure still further, the yielding of the metal will result in a permanent set in the metal and will cause a redistribution of the stresses in the metal. If the pressure is relieved, there will be stresses near the hole due to the set in the material, and if the pressure be high enough, these stresses are such that on applying and relieving the pressure a number of times the material will fail at the hole through a fatigue action. The safe working pressure for a drum of this sort would therefore be much higher for service conditions where it would be subjected to a reasonably steady pressure or where the pressure would be only occasionally applied and released than it would be if used under a continually fluctuating pressure.

Another question to consider is the distribution of strains due to the thickness of the walls of a vessel which causes the stresses on the inside of the shell in a thick-walled vessel to be greater than those on the outside when the stresses are within the elastic range of the material. With ductile material the stresses will be more or less equalized from the inside to the outside of a thick drum on increasing the pressure to a point where the proportional limit of the most highly strained parts of the material is exceeded. On relieving the pressure there would be tensile stresses on the outside of the shell and compressive stresses on the inside of the shell. An overstrained drum of the sort could be operated more safely at a steady or at a reasonably steady pressure than at a continually fluctuating pressure, and in this respect the influence tending to metal fatigue would be similar to the action at the sides of a hole which has been referred to.

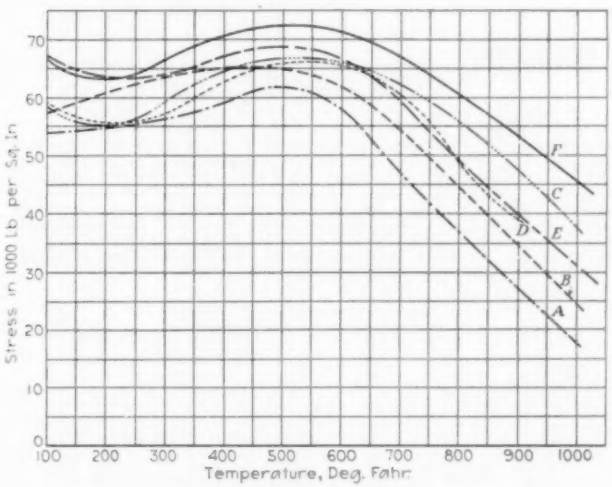

FIG. 1 TENSILE STRENGTHS FOR CARBON STEELS

(*A*, 0.13-C steel, White, Eng. Res. Bull., Univ. of Mich., 1928; *B*, 0.17-C rolled bar, *Valve World*, August, 1928, p. 269; *C*, 0.17-C firebox steel, French, B. S. Tech. Papers, 219, p. 690.)

Another factor which results in strain in the material of a shell which must be considered in establishing the working stress is the effect of heat applied to the outside of the shell and transmitted to the inside of the shell. This is important in boiler tubes, especially at the higher working pressures, and in any vessel which is subjected to heat while under pressure. In this case, as in the others, straining the material results in equalization of the stress from the outside to the inside when subjected to heat, and on allowing the tube or vessel to cool down counter-stresses will be set up, so that a fluctuating tempera-

ture has a similar effect on reducing the safe working stress as a fluctuating pressure.

All this shows that the safe working stresses should be based on the results secured through experience and practical service rather than on any theoretical ground.

Experiments of a comparatively recent date have shown the

importance of considering the plastic flow of steel when under stress at high temperatures. Much work has been done in determining the rate of extension or "creep" at different temperatures. Certain of the published results derived from these experiments have led to some apprehension in the employment of stresses that have been considered safe, and it is the object of this paper to overcome such apprehension for the particular stresses which are discussed.

It must be remembered that it was necessary to set working stresses for higher temperatures long before the results of creep tests were available. The working stresses given in Table 1 for temperatures ranging from ordinary room temperatures up to 800 deg. fahr. were so set and the results secured in practice have shown that the stresses which were so set are safe.

Over ten years ago it was necessary to set the working stress for an oil still to be made by The Babcock & Wilcox Co. with riveted drums of $1^3/_4$-in. plate for a temperature of 825 deg. fahr. The steel selected was a boiler steel in conformity with the specifications of the A.S.M.E. Boiler Code, having a minimum tensile strength of 55,000 lb. per sq. in. After a study of the results obtained in oil-still and superheater practice and of all available data on the ultimate strength, yield point, and proportional limits of the steel determined by quick time tests, the working stress was set at 7180 lb. per sq. in., based on the working pressure which was carefully regulated, and 7950 lb. per sq. in., based on the setting of the safety valves. A number of stills were built for these stresses and operated satisfactorily.

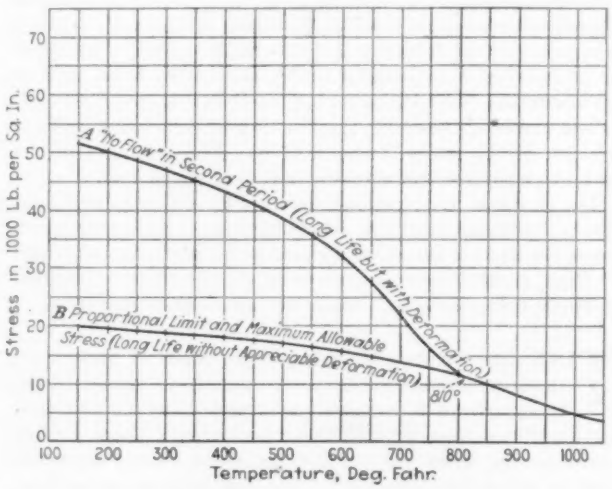

FIG. 4 CREEP AND PROPORTIONAL LIMIT VALUES FOR CARBON STEEL

(*A* and *B*, 0.24-C steel, H. J. French, B. S. Tech. Papers, no. 296.)

From the results of this experience and that secured in superheater and boiler practice a working stress of 8000 lb. per sq. in. at 800 deg. fahr. was established, and also the stresses for temperatures lower than this.

In establishing the working stresses for higher temperatures than 800 deg. fahr., which was done at a later date, the creep-test results then available were made use of, and the figure of 8000 lb. per sq. in. for a temperature of 800 deg. fahr. was scaled down in proportion to the falling off of the stresses to produce creep. The first curve of creep stresses published by Mr. H. J. French of the Bureau of Standards was used, and the working stress for a given temperature taken at $^2/_3$ of the creep stress shown by Mr. French's curve.

It should be borne in mind that the effect of creep is to equalize the stresses and to make the conditions better in this respect.

The stresses determined in the way described are given in Table 1, together with the stresses used in the design of superheater headers for an A.S.M.E. Boiler Code steel having a minimum tensile strength of 62,000 lb. per sq. in.

Fig. 1 gives curves showing the ultimate strength of various steels determined by quick time tests at different temperatures. Fig. 2 gives the yield points by quick time tests, Fig. 3 the proportional-limit points by quick time tests, and Fig. 4 the first curve of creep stresses published by Mr. French.

Much has been done in establishing creep stresses since we set the stresses given in Table 1. Professor F. H. Norton of the Massachusetts Institute of Technology conducted a most accurate and painstaking investigation, the results of which are published in his book entitled, "Creep of Steel at High Temperatures." He made a great many tests of long-time duration on 17 different alloy steels at temperatures ranging from 1000 to 1500 deg. fahr. The chemical analyses, physical properties, and photomicrographs to show the structure of the different steels are given in his book.

TABLE 1 WORKING STRESSES FOR DRUMS OF BOILERS AND PRESSURE VESSELS AND FOR SUPERHEATER HEADERS

[a] Shaded down to allow for the falling off of the yield point and the proportional limit.

Fig. 5 and Table 2 are taken from Professor Norton's book, showing the results of his experiments on three carbon steels at temperatures of 900 and 1000 deg. fahr., and some tests that he made as a continuation of his research on the alloy steels.

The results obtained by a number of experiments for carbon steel are shown in Figs. 6 and 7. These figures and the names of the experimenters and references and brief description of their work given in Table 3 and in the Bibliography are taken from Professor Norton's book. There is a wide discrepancy in some of the results obtained by different experimenters, depending on the test methods, duration of the tests, and the method of interpreting results. There is need of more exact data for temperatures below 900 deg. fahr. It is hoped that correspondingly accurate experiments to those of Professor Norton will be made for a lower range of temperature.

It will be well to consider the accuracy of the figures given in Table 1 in view of the data which became available after it was prepared. A paper by Messrs. French, Cross, and Peterson published by the Bureau of Standards, No. 362, contains a curve for 0.24-C steel which gives lower values for the creep stresses than the first curve published by French. The curve is on the basis of the stress producing 0.1 per cent or less elongation in 1000 hours or 1 per cent elongation or less in 10,000 hours. The statement is made that it was only possible to estimate the maximum stresses which will permit certain selected life with certain deformation, and that this explanation was made to avoid misunderstanding considering the accuracy of the data or the method of arriving at the numerical values. The method of extrapolation used in obtaining the results was different from that employed by Professor Norton, and if Professor Norton's method is applied to the experimental results shown for a 0.24-C steel at 810 deg. fahr. in Fig. 10 of the paper, the stress to produce 1 per cent of creep in 10,000 hours would be 12,500 lb. per sq. in., whereas curve No. 5 in Fig. 21 of the paper gives a stress of about 9000 lb. per sq. in. for this temperature. The figure of 12,500 lb. per sq. in. for the stress to produce 1 per cent of creep in 10,000 hours corresponds closely to the creep stress of 12,000 lb. per sq. in. given in Table 1.

The results of Professor Norton's tests given in Fig. 5 and the data contained in Table 2 give a stress of 10,500 lb. per sq. in. to produce a creep of 1 per cent in 10,000 hours for a 0.2 per cent carbon steel at 900 deg. fahr., which is considerably higher than the creep stress given by Mr. French's first curve as contained in Table 1 and shows that the creep stresses given in Table 1 may be considered as conservative.

The method of extrapolation used by Professor Norton is shown in Fig. 5. The stresses to produce a given rate of creep at a certain temperature are plotted against the rate of creep on logarithmic paper, the results in Professor Norton's experiments giving nearly a straight line. This method of extrapolation is more accurate than one employing a widely curved line. The many tests and the wide range and consistency of his experiments show that the results obtained by his method of extrapolation to the extent that he used it are reliable.

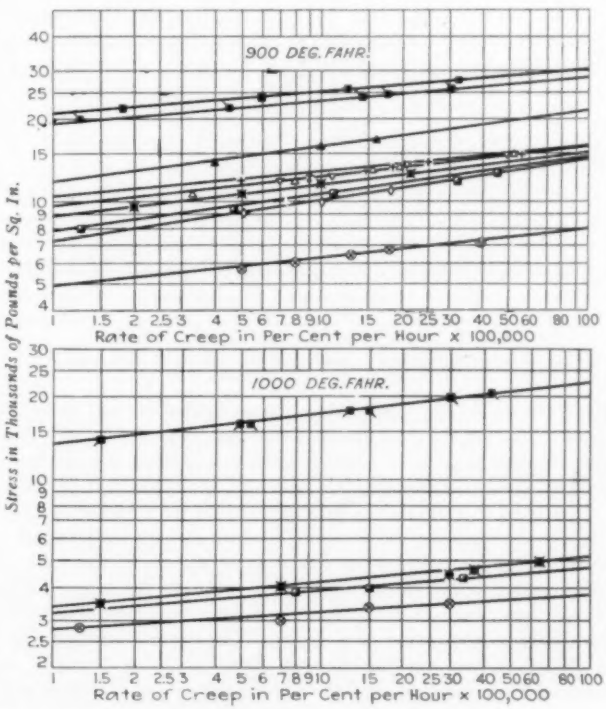

Fig. 5 Runs at 900 and 1000 Deg. Fahr.

TABLE 2 CREEP STRESS[2]

Steel	Symbol	Life with 1% elongation 100,000 hr. 900°F.	1000°F.	10,000 hr. 900°F.	1000°F.
E	■	20,500	....	25,000	....
E (rerun at 1000°F.)	◥	19,500	....	23,500	....
E (rerun at 1100°F.)	◧	....	13,500	....	17,500
E (rerun at 1200°F.)	◪	....	13,500	....	17,500
G	▲	12,000	....	16,000	....
M	+	10,500	....	13,000	....
P	▽	9,600	....	12,500	....
O	△	9,600	....	12,500	....
0.42% carbon steel	✖	8,800	3,500	11,500	4,200
0.20% carbon steel	◘	7,800	3,200	10,500	3,900
0.08% carbon steel	⊕	4,900	2,800	6,300	3,300
I	◊	7,200	....	10,000	....

The results obtained by Professor Norton, employing his method of extrapolation, would indicate that a stress of 2/3 that required to produce 1 per cent of creep in 10,000 hours would be equivalent to from 80 to 90 per cent of the stress required to produce a rate of creep of 1 per cent in 100,000 hours and that the stress would correspond to 1 per cent of elongation

[2] For composition of steels designated by the letters in this table see Table 4.

due to creep in 25 to 50 years. These figures are not given as absolute values, but to show that a reduction in the stress below that required to produce 1 per cent of creep in 100,000 hours has a marked effect in increasing the time for a given amount of creep.

It is hard to formulate a rule that should be generally applicable for determining the working stresses at high temperatures. A variation in temperature has a great effect on the rate of creep, and in some cases it is hard to estimate the temperature of the metal, such as in those where heat is transmitted through the metal to the inside of a vessel. The general method used in obtaining the working stresses given in Table 1 might be followed for conditions similar to those for drums of boilers and pressure vessels and for superheater headers, viz.:

For the higher temperatures where the steel is distinctly plastic, use $^2/_3$ of the stress required to produce a rate of creep not to exceed 1 per cent in 100,000 hours. In case of doubt, use the most conservative figure in view of the many uncertain elements.

For the lower temperatures use the same working stress as at ordinary room temperatures, provided the ultimate strength determined by a quick time test at the particular temperature divided by the factor of safety is as great as the working stress for ordinary room temperatures, and also provided the stress does not exceed $^1/_3$ of that required to produce a rate of creep not to exceed 1 per cent in 100,000 hours.

In the figures given in Table 1 the working stresses were shaded down for 750 deg. fahr., which comes at a point where a horizontal straight line on plotting the working stresses would meet a curve which decreases as the temperature increases. This shading down was done in order to allow for the falling off of the yield point and the proportional limit at these points, with the idea that this feature is important in a riveted structure.

It may be claimed that the yield points and proportional-limit points should enter any rule for establishing the working stresses. For ordinary temperatures it is common practice to base the working stresses on the ultimate strength of the material rather than on the yield point or the proportional-limit point and to use the yield point only in specifying the physical properties of the material to be employed. There have been proposals to base working stresses on the yield point, or on the so-called elastic limit or proportional-limit points (in fact in some cases the working stresses are obtained in this way), but it still remains common practice to base the stresses on the ultimate strength of the material. An objection to basing the working stresses on the yield point, or what for many years was known as the elastic limit, or on the proportional-limit point, is that there are apt to be wide variations in the results for these points determined by different laboratories for the identical steel,

whereas there are not as wide variations in the results for the ultimate strength.

The many creep tests that have been and are being made are of great value to the industry. Higher and higher metal temperatures are being employed in some fields of work, and the results secured by creep tests assume more and more importance. A greater fund of experience is also becoming available as a guide to the dependability of working stresses at high temperatures, and combining this experience with the results secured by creep tests will do much to rationalize the problem.

It is hoped that the working stresses used for steel at high temperatures by different parties will be submitted in order that we may all get together in establishing a rule that will represent good practice.

2 J. H. S. Dickenson, "The Flow of Steels at a Red Heat," *Engineering*, 114, p. 326, p. 378. The paper considers the creep of steels, giving a description of the apparatus used and data at one stress on a number of steels.

3 F. C. Lea, "Effect of Low and High Temperatures on Materials." *Proc. Inst. Mech. Engrs.*, 2, p. 1053. Very complete tests are made on the various mechanical properties of steel over a wide range of temperatures. This is one of the first investigations where the value of long-time tests is realized. The influence of strain hardening is also discussed.

4 J. Cournot and K. Sasagawa, "Contribution à l'Étude de la Viscosite des Alliages à Temperature Elevée." *Rev. Met. Mem.*, 22, p. 753, also "Comptes Rendus," 181, 0. 661. The flow of several steels is studied at various temperatures. The specimens are in the form of wires, and the duration of the test is not long, but the extension is measured precisely. The apparatus and method of test are fully described.

5 T. D. Lynch, N. L. Mochel, and P. G. McVetty, "The Tensile Properties of Metals at High Temperatures." Proc. A.S.T.M., 25, 11, p. 5. Data on the tensile properties of various materials at temperatures up to 930 deg. fahr. are collected. Some data on long-time tests are given.

6 A. E. White and C. L. Clark, "Properties of Boiler Tubing at Elevated Temperatures Determined by Expansion." Trans. A.S.S.T., 11, No. 1, p. 73. The object of this investigation was to determine the safe working loads for low-carbon steel tubes from 900 deg. to 1500 deg. fahr., but the data are rather incomplete. It is pointed out that at the higher temperatures creep occurs much below the proportional limit.

7 A. Pomp and A. Dahmen, "Entwicklung eines Abgekurtzten Prufverfahrens zur Ermittlung der Dauerstandtfestigheit von Stahl bei Erhöhten Temperaturen." Mitt. a. d. Kaiser-Wilhelm-Inst. f. Eisenforchung zu Dussel, IX, no. 3. This is an extensive article on creep measurements. The work of others is reviewed, with a description of their testing apparatus. Creep data on several steels are given, although the length of test at one load was only a few hours. The limiting creep stress is compared with the elastic limit.

8 H. J. Tapsell and W. J. Clenshaw, "Properties of Metals at High Temperatures." 1, Mechanical properties of Armco iron, 0.17 per cent carbon steel, and 0.24 per cent carbon steel with special reference to creep. Department of Scientific and Industrial Research, Engineering Research, special report No. 1, published under authority of His Majesty's Stationery Office. Comprehensive tests are described on the mechanical properties of low-carbon steels. The value of creep tests is discussed, and considerable data are given. A good list of references and creep results by other experimenters are given.

9 H. J. French, H. C. Cross, and A. A. Peterson, "Creep in Five Steels at Different Temperatures." B. S. Tech. Papers, No. 362. Creep tests are made on five types of steel up to 1350 deg. fahr, with more than the usual understanding of the difficulties involved.

10 T. McLean Jasper, "Strength of Steels at Elevated Temperatures, With Particular Reference to Factor of Safety." *Power*, 67, p. 446. This article discusses safety factors and design for high-temperature steel structures. Creep values for two low-carbon steels are given.

11 H. J. Tapsell, "Properties of Materials at High Temperatures," 3, Note on the "creep" of Armco iron. Department of Scientific and Industrial Research, Engineering Research, special report No. 6 published under authority of His Majesty's Stationery Office. The creep of iron is studied particularly at temperatures below 400 deg. fahr. Strain hardening and temperature softening are discussed in relation to creep.

12 C. L. Clark and A. E. White, "The Stability of Metals at Elevated Temperatures." Eng. Res. Bull., Univ. of Michigan. The authors compare the creep stress in long-time tests with the proportional limit in short tests. At low temperatures the agreement is good, but at high temperatures they find no definite limiting creep value. They believe that at a certain temperature the strength of the crystals is equal to that of the boundaries. Above this temperature the amorphous boundaries are the weaker and below it the crystals yield first.

Discussion

A. E. White.[3] Much has been written on this subject, but most of it has been of a character such that it has been necessary for engineers and designers to use their own judgment as to what stresses to employ. One finds in this paper very definite recommendations as to working stresses.

The entire question of the characteristics of metals at high temperatures is exceedingly involved. The results of the findings of many investigators are widely divergent, as evidenced by the variation in values obtained by various investigators as given in Figs. 6 and 7 of the paper. When one recognizes that creep values for carbon steels as given by various investigators in Fig. 6 vary at 800 deg. fahr. from a little above 8000 lb. per sq. in. to 44,000 lb. per sq. in., or, as shown in Fig. 7, at the same temperature from 8000 lb. to 56,000 lb., one can realize the discrepancies which exist. These differences are, without doubt, due in slight degree to differences in composition, but to a greater degree to the different methods employed in the testing of the metals and to the methods employed in arriving at the results.

The writer is in general accord with the working stresses given in Table 1. This conclusion he has reached because of the following:

1 The creep values given in the table would be among the most conservative of the creep values given in Figs. 6 and 7.

2 Though Professor Norton, who did the work of procuring the creep values, did not carry his findings beyond 400 hours, yet the writer feels they represent a high degree of accuracy because of the many tests made and the wide range and consistency of the experiments.

3 To date the writer knows of no failures which have resulted when working stresses given in Table 1 have been used.

C. L. Clark.[4] A paper of this type is very valuable in that it allows results obtained in actual commercial practice to be compared with those obtained in the laboratory. Since the stresses to which the metals in actual use are subjected are not simple tension, as is the case in the laboratory test, and since the temperature and stress variations in actual use are much greater than those encountered in the refined laboratory test, it is surprising that there is such a close agreement between the creep values reported by Professor Norton and the safe working stresses previously adopted by the Babcock & Wilcox Company.

Care must be exercised in the selection of safe working loads for periods of 10,000 or 100,000 hours on the basis of laboratory tests lasting only a relatively few hours. It is obvious that with the large number of steels to be investigated and the wide temperature range to be covered, each test cannot be continued for thousands of hours. They should be continued for a sufficient length of time, however, so that the true shape of the time-elongation curve can be determined. The values reported in this paper were obtained as the result of tests lasting 400 hours, and accordingly should be more representative of actual conditions than those obtained over a period of a few days.

The creep apparatus at the University of Michigan has been recently modified so that the elongation of the test specimen can be determined directly to 2.8 millionths of an inch. Results obtained from a test on a certain ferrous alloy at 1000 deg. fahr. show that, for at least the first 300 hours, the elongation is not directly proportional to the time, but that the time-elongation curve assumes more the form of a parabola.

It is the writer's belief that at least one representative type of metal (pearlitic, austenitic, austenitic + carbides, etc.) should be tested at each temperature in question, that the test should be continued for several thousand hours, and the elongation determined accurately to a few millionths of an inch so that the true shape of the time-elongation curve can be definitely settled for once and for all. Also in this work the results obtained should be plotted to a scale comparable with the accuracy of the readings. Nothing is to be gained if readings accurate to a few millionths are plotted to a scale suitable for readings accurate to a few thousandths.

[3] Professor of Metallurgical Engineering and Director of Department of Engineering Research, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

[4] Department of Engineering Research, University of Michigan, Ann Arbor, Mich.

The above series of tests is believed to be of the utmost importance because practically every limiting creep value reported in literature is based on the assumption that the elongation is directly proportional to the time. If this can be definitely proved either one way or the other, greater reliance could be placed on reported limiting creep values.

GEO. A. ORROK.[5] The author has presented the kind of a paper which best represents the ideals of the Society: a statement of present-day practice and its difficulties, and an account of carefully conducted sets of experiments, followed by a set of definite recommendations for future practice. Most engineers will agree with him that the results secured by rules of boiler construction based on experience rather than theory have justified his statement. But an early engineer once said that where experience and theory did not agree, either the practice was poor or the theory imperfect. To the writer it would appear that the author was using both experience and theory and that little conflict was obtained.

In every construction exposed to pressure and temperature strains we have the main loading, steady or fluctuating within limits more or less determinate, and the additional loadings due to eccentricity, type of construction, and the conditions of operation. The main loading is taken care of by calculating the stresses, and the indefinite loadings are covered by a margin of strength; the ratio of main stress to ultimate stress is miscalled the "factor of safety."

For the sake of simplicity, expediency, or legal definiteness, much clearness has been sacrificed. The widespread use of factors of safety referred to main stresses has fostered an ignorance of actual stress conditions, and the legalization of these factors, however necessary, is nevertheless a decided deterrent in the general progress toward the knowledge of structures.

The steam boiler is probably the most representative construction where the magnitude of indefinite additional stresses reaches or surpasses that of the stresses due to the main load. We may freely admit that our theoretical knowledge of the strength of steel at elevated temperature is not large; furthermore our calculations of stresses are only conventional forms of approximation, miraculously working together with the factor of safety—but still we must design new boilers, for pressures and temperatures beyond previous practice. The remedy for this unfortunate condition must be sought in a series of successive steps undertaken to evaluate the additional stresses in order of their magnitude and to incorporate them in the regular boiler-strength calculations. The investigation of thermal stresses in tubes and drums and the localized stresses around holes should be the first step.

In the writer's paper on high-pressure boilers (1927)[6] the high values of thermal stresses in boiler tubes were indicated, but probably very few are aware of the fact that in most boiler tubes exposed to radiation the external fibers of the metal are in a state of compression in spite of inner steam pressure and that the thermal stresses due to heat transfer exceed those due to the pressure of steam. The question of concentrated stresses around holes and edges has been dealt with theoretically by many mathematicians, but their work is neglected in boiler practice.

Some years ago the phenomena of creep in steel became known, and now with the 1000-deg. fahr. steam temperatures entering the power-plant field it requires our immediate attention. In the presence of this phenomenon we are apparently losing our criteria and margins of stability. Dr. Jacobus advises the use of two-thirds of the creep limit stress as determined by experiment for long duration; 100,000 hours, for instance. The conception of stress margin is deeply rooted in the engineering mind, due to the long years spent on studies of cold structures. The range of temperature fluctuation in boiler parts is much wider than the range of variable stresses, and the stability of the structure, be it a drum, a tube, or a valve, depends to a very much greater extent on temperature than on the stress.

The principal stresses in boiler parts are not likely to fluctuate to a great extent, but the temperatures are, and the 100 deg. fahr. nominal temperature margin if acceptable for a drum is quite low for a boiler tube or superheated-steam circuit. Cases are known of very great variations of temperature. At Langerbrugge (Belgium) the 850-deg. fahr. normal steam temperature rose for $1^1/_2$ hours to 1056 deg. fahr., and usually fluctuates between 800 and 950 deg. fahr. At Gennevilliers one turbine designed for 750 deg. was getting steam up to 1020 deg. fahr. for prolonged periods. In American stations 100 deg. fahr. variations in total steam temperature have been common. Adding here the indefinite increment of temperature due to heat transfer at varying cleanliness, we see that the temperature of the metal will be the factor controlling the stability of the structure.

If all the failures and troubles are taken by and large, the majority of them will be found due to local stresses and hence two-thirds of the creep limit for the main conventional stress cannot be considered as equivalent to one-fifth of the ultimate strength cold nor to one-third of the elastic limit cold. However, one-third of the creep limit might be equivalent for stresses of long duration. For accidental short-duration stresses, two-thirds of the creep limit appears to be sufficient. This reasoning is valid at constant temperature, but in actual conditions of boiler operation many parts are subject to local overheating, and the average working temperature may vary within such limits that the stresses as a criterion of metal condition become quite misleading, their effect far exceeding the design limits.

Dr. Jacobus' conception of a design for a definite period of time with a given ultimate creep deserves serious attention. This idea was first put forward by Bailey in England. During this period the average working temperature will be increased by the integrated increments due to the variation in operation and by a constant fraction due to heat transfer. For instance, a 750-deg. fahr. steam plant during 100,000 hours must be considered as working at $750° + 30° + (850° - 759°)/n$, where 30° is added to heat transfer, 850° is the accidental maximum, and n is a factor of unevenness of operation; the total, at $n = 5$, will be 800 deg. fahr. This increase of average working temperature by 50 deg. fahr. lowers the creep limit of 12,000 lb. per sq. in. to 10,000 lb. per sq. in., using up half of the reserve stability calculated at two-thirds creep limit stress at 750 deg. fahr. In the range 900–950 deg. fahr. the additional 50 deg. use up all the reserve. It is clear thus that the stress margin of stability represented by one-third of creep limit stress vanishes quickly at a slight unavoidable increase of temperature, and cannot be taken as a criterion of long-period stability.

The logical method to use in the selection of working stresses, first proposed by Mellanby and Kerr, that of temperature margins, should be preferred. But whatever system of securing the reserve strength may be selected, the question of thermal and localized stresses must be fully investigated, and the final margin in the form of stress or temperature chosen in respect to the total calculable actual stress.

N. ARTSAY.[7] There are very few parts in boilers and engines that are not subject to combined stresses. The refinement of calculations which introduces thermal stresses and creep limits

[5] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[6] Trans. A.S.M.E., vol. 49–50 (1927–1928), paper FSP-50-32.

[7] Principal Assistant of Geo. A. Orrok, Consulting Engineer, New York City.

certainly should be preceded by estimation of the combined effect of principal apparent stresses. For structures working below, say, 600 deg. fahr. there are three theories of failure under load. The first, that of exceeded principal apparent stresses, failed utterly. The second, that of exceeded true stress accompanying the maximum principal deformation, is being superseded now by the third theory, that of exceeded maximum shearing stress. Considering the creep phenomena in structures with combined stresses, we are without any theory of strength whatever.

The experimental data on creep at pure tension are already available in sufficient quantities, but the application of these results is hazardous or, at the other extreme, may involve much waste of material. For instance, if we have a cylindrical closed vessel under cold pressure the true stress will be $a\ (1 - {}^1/_2 m)$, where s is the principal hoop stress and m is Poisson's ratio. It seems thus that in a closed vessel a higher principal apparent stress could be allowed. But, while in an open cylinder subject to hoop stress the increment of volume is $x\ (1 - 2m)$, where x is the deformation, the increment of volume in the case of a closed cylindrical vessel is ${}^3/_2 x - 3\ xm$, which is greater. There are many considerations to support the view that the ability of metals to creep or to redistribute the molecular clusters is proportional to the increment of volume of the metal due to stresses, and hence in the case of two principal tensions the true measure of stress for the creep estimation will be a stress larger than the principal apparent stress.

An experiment to determine creep in the metal of a closed cylindrical vessel containing a neutral gas under pressure—nitrogen, for instance—made parallel with a creep determination in pure tension, will shed some light on this important question.

J. J. KANTER.[8] There can be little doubt that the distribution of creep stress in steel pressure vessels under operating conditions can by no manner or means be considered the same as in a tension-test specimen under constant load. While it is true that creep can redistribute stresses, it must be borne in mind that under fiber-stress conditions the ligaments of metal will be subjected to a range of creep-stress moments.

In view of this rather complicated stress condition, it would appear worth while to turn more attention to the problem of conducting creep tests on metal under fiber stresses as well as straight tension. Such tests might serve to throw some light on the discrepancies known to exist between the so-called creep limits and what has been found feasible for successful operation and service.

All of the difference between test data and service should not be attributed to thermal gradients alone. Until actual studies are made on fiber-stress creep, attempts at explanation remain highly speculative. A very important factor entering into creep phenomena, seemingly neglected in the paper, is creep arrest, or what French terms a transition from "primary" to "secondary" flow. Further studies upon this effect, made at Crane Co. laboratories, show continuous deceleration of creep rates on some tests of as much as one year's duration, load and temperature constant.

The classification of the rapid early creep and the subsequent slower rate now appears somewhat arbitrary. Fiber-stress creep is accompanied perhaps by an effect somewhat similar or analogous to the retardation found in tension. From a speculative standpoint, it even appears reasonable that transition from "primary" to "secondary" may be more pronounced in tube walls than for bars under tension. If the stress on the most strained fiber tends toward equalization, and therefore more creep than in less strained fibers, the outer fiber of a tube section under internal pressure should pass beyond the primary creep stage soonest.

[8] Crane Co., Chicago, Ill.

The result of such a condition, it is readily seen, is to bolster up the outer portion of the section to a certain extent, and the net rate of radial creep should retard much faster than it does in tension. This conception perhaps affords a slight clew to the reason why actual service proves a much greater load-carrying ability for tubes than appears possible from the results of long-time testing.

It is to be regretted that Professor F. H. Norton did not consider creep deceleration in his excellent series of tests. The method pursued in his tests, it appears, was to increase the testing load periodically, after several hundred hours of observation, until a suitable range of stresses and creep rates had been tried. While this procedure is somewhat economical of time and requires but one specimen for each temperature investigated, it leaves one of the natural and fundamental creep conditions entirely out of the picture.

Tests made at temperatures of 900 and 1000 deg. fahr. show that deceleration at "creep-limit" stresses is of a very considerable order. Moreover the total creep found for bars brought to load by the step method leads to much different values for extrapolated rates of creep than do the tests made, each using a separate specimen. (This was proved in the tests by the Crane Company.)

In view of these facts, a more rational evaluation of creep data would be had if total creep over a convenient period, and inclusive of the rapid initial flow, were considered.

It hardly need be said that the closer and more completely we adhere to observed facts, the greater will be the practical worth of the tests.

H. F. MOORE.[9] The use of Norton's logarithmic-plot method for determining the stress corresponding to a definite and very slow rate of "creep" under high temperature, instead of attempting to determine the stress limit for zero creep, is a very interesting feature of Dr. Jacobus' paper. The attempt to determine an absolute "creep limit" seems as unsatisfactory as the attempt to determine an absolute elastic limit.

The situation we face in attempting to choose a criterion for allowable stress at high temperatures seems to be analogous to that existing some ten years ago in the field of failure of metals under repeated stress. At that time there was not available any considerable amount of test data for long-time fatigue tests, and it was not certain that there was any "fatigue limit" below which an indefinitely large number of repetitions of stress could be withstood without fracture. In 1910 Professor Basquin, of Northwestern University, proposed for repeated stress a method of determination of safe stress for a given "life" of material which was very similar to that proposed by Professor Norton for "creep" under high temperature. Professor Basquin's method gave safe results, but long-time fatigue tests have given clear indications that there is a well-defined "fatigue limit" for most, if not all, metals.

Whether "creep" tests extending over longer periods than have been used for any tests up to the present will indicate a "creep limit" corresponding to the fatigue limit under repeated stress is a matter for the future to decide, and the time required for such a decision will probably be even longer than that needed to establish the existence of a fatigue limit. Meanwhile Professor Norton's method seems to be one which may be made to yield safe and reliable results for determining limiting stresses for metal parts in danger of failure by "creep" under high temperatures, and Dr. Jacobus' use of that method is to be regarded as a step in advance.

[9] Research Professor of Engineering Materials, University of Illinois, Urbana, Ill. Mem. A.S.M.E.

ALBERT SAUVEUR.[10] Dr. Jacobus deals with a problem that must command the attention of engineers and metallurgists until it is satisfactorily solved. His treatment of the subject is rational and illuminating. The writer finds himself in full agreement with him when he expresses the opinion that a closer relation exists between the creep value of a steel and its tensile

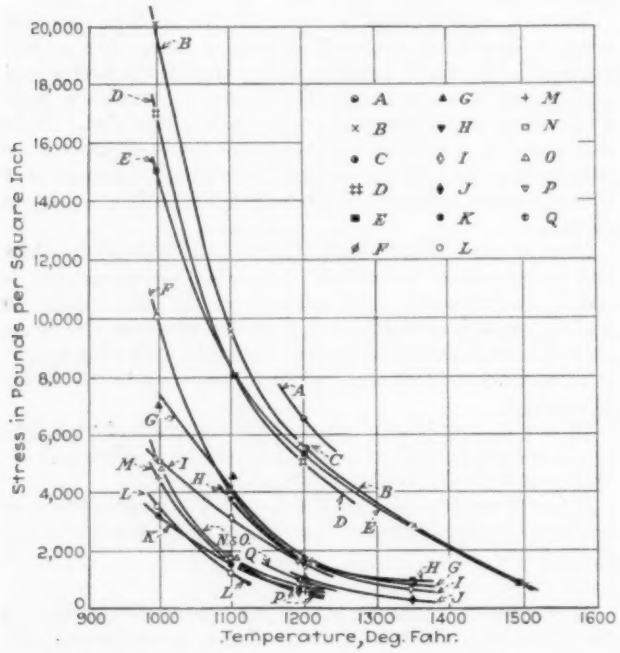

FIG. 8 CREEP STRESS FOR A LIFE OF 100,000 HOURS WITH 1 PER CENT ELONGATION

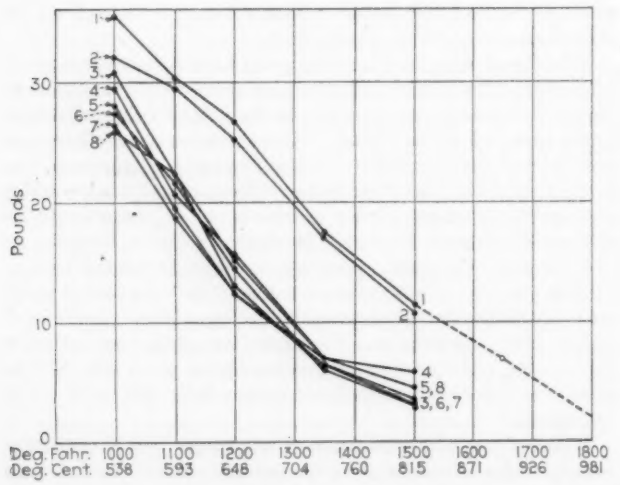

FIG. 9 RESULTS OF TORSION TEST AT TEMPERATURES SELECTED BY PROFESSOR NORTON

strength than between the former and the elastic limit or yield point.

The writer has had the opportunity to submit to torsional stress at elevated temperatures some of the steels used by Prof. F. H. Norton in his study of the creep of steel.[11] These steels included five nickel-chromium austenitic steels and twelve non-austenitic alloy steels and carbon steels. The results obtained by Professor Norton are shown graphically in Fig. 8 for a creep stress for a life of 100,000 hours with 1 per cent elongation. It will be seen that the austenitic steels (A, B, C, D, and E) are distinctly separated from all other steels, and that their resistance to creep is considerably greater at all temperatures between 1000 and 1400 deg. fahr.

Seven of the steels used by Professor Norton—namely, two nickel-chromium austenitic steels, three non-austenitic chromium steels, one nickel steel, and one low-carbon steel—were subjected to our torsion test at the temperatures selected by Professor Norton, namely, 1000, 1100, 1200, 1350, and 1500 deg. fahr. The actual torsional strength of the test bars in pounds[12] are plotted against temperatures in Fig. 9. The similarity between this diagram and Professor Norton's cannot fail to attract attention. The austenitic steels are again distinctly in a class by themselves. Had we used this simple and rapid twisting test as a means of ascertaining the relative creep values of these seven steels, our conclusions would have been quite similar to those reached by Professor Norton after many months of delicate testing. From the aspect of both sets of curves, one might wonder whether at temperatures in excess of 1650 deg. fahr., when all steels are austenitic, they might not also have substantially the same creep values.

F. H. NORTON.[13] The writer is sure that this interesting paper will be of great assistance to designers, as it summarizes and puts into workable form the scattered data on the properties of steel at high temperatures. Attention is called to the difference in stresses caused by plastic rather than elastic deformation. We greatly need more information on the distribution of stress under plastic conditions, and better theories for computing plastic flow in irregular objects. It seems evident from the scanty data at hand that the stress concentration usually found in irregular elastic bodies are much reduced in plastic objects.

We also need more data on the creep of steels at lower rates in order to determine how the rate of creep falls off with the load, and whether there is any limit below which plastic flow ceases. It has recently been noticed that the pendulums in astronomical clocks show a very slight yearly elongation, which has been attributed to plastic flow, even under these conditions of low load and low temperature. Perhaps in no other way could such delicate measurements of length change be made. At the Massachusetts Institute of Technology we are now conducting some creep tests which will run for a long enough time to detect creep under conditions of comparatively low loadings, so that we may be able to extend our data in this direction.

JOHN M. LESSELLS.[14] The paper in attempting to put on a working basis for design the data obtained on the tests on steel at high temperatures is to be highly commended.

The writer fully agrees with Mr. Orrok that it is more dangerous to have an increase in temperature than an increase in pressure. In this respect, the paper by Mr. H. L. Guy[15] is worthy of attention. The question of temperature variation is an important phase of choice of working stresses.

As to whether steel which has apparently ceased to creep while

subjected to high temperature will ever show later tendencies to creep, will depend on whether the temperature is sufficient to overcome the cold-working effects due to stressing. We can consider creep as the predominance of annealing over strain hardening.

The author has directed attention to working stresses for parts where comparatively large deformation can be allowed. There are other machine parts where the working stress must be chosen on the basis of permissible deformation, and in high-temperature testing these two phases of the work must always be considered.[16] This thought suggests that the title should be restricted to working stresses for steel at high temperatures as applied to drums and boilers.

Jos. Kaye Wood.[17] The writer feels that the publication of this paper is well timed and that the words of advice regarding greater activity and cooperation in this field of research should be given serious consideration. In this respect the author voices the opinions expressed by the writer in an article[18] published by him just prior to the presentation of the paper. In addition to stressing the inadvisability of using the yield point or proportional limit as the basic physical property for controlling the safe working stress, the writer also advocated a factor of safety equal to 1.5 when using the creep limit as the basic physical property. Using a factor of safety of 1.5 is equivalent to taking two-thirds of the creep limit as advised by Dr. Jacobus. The tensile strength is not as satisfactory as the creep limit for determining safe working stresses unless the factor of safety is based upon long experience as in boiler practice. Furthermore a basic physical property that requires a larger factor of safety is less reliable than one that requires a smaller factor of safety, provided both physical properties are determined accurately.

In his article previously quoted, the writer reports a creep limit at 932 deg. fahr., equal to 7000 lb. per sq. in. for firebox steel, which agrees closely with Dr. Jacobus' results. In the same article a creep limit of 14,000 lb. per sq. in. at 932 deg. fahr. is reported for vanadium steel. For these same steels at the same temperatures the proportional limits are given as 8000 lb. per sq. in. for the firebox steel and 6000 lb. per sq. in. for the vanadium steel. These comparative figures show how misleading the use of the proportional limit may be when employed as a basic physical property, even when this property is carefully determined, as was done in this case.

F. P. Coffin.[19] The question has been raised, by one of the previous speakers, as to the effect of different percentages of carbon on the strength of steel at elevated temperatures.

Some tests have been made in the Research Laboratory of the General Electric Company to determine this point, using steel with carbon contents of 0.16 and 0.40 per cent, respectively, over the temperature range from 400 to 650 deg. cent. (752 to 1202 deg. fahr.). Both steels were annealed at 800 deg. cent. (1472 deg. fahr.), and were tested at 400, 500, 600, and 650 deg. cent. The flow limits were almost identical at temperatures from 500 to 600 deg. cent. with the curve heading toward zero strength at the mean critical point of 723 deg. cent. (1334 deg. fahr.). At 400 deg. cent. the 0.40 carbon steel had about 50 per cent greater strength than the 0.16 carbon steel. The approximate flow limits for 1 per cent elongation in 10 years were 18,000 and 12,000 lb. per sq. in., respectively.

Another specimen of the same 0.40 carbon steel is now being tested at 450 deg. cent. (842 deg. fahr.) after a preliminary normalizing treatment in which it was air-cooled from 900 deg. cent. (1652 deg. fahr.) and drawn at 600 deg. cent. (1112 deg. fahr.). The test is still in progress, but the indications are that this specimen will fall on the same flow-limit curve as the annealed 0.16 carbon steel.

So far as we have carried this investigation, the indications are that the flow-limit curves of the two types of steel converge a little below 450 deg. cent. and that the effects of different heat treatments are equalized at 450 deg. by the annealing effect incident to holding the steel at this temperature during the test which has been under way nearly four weeks.

We have also found that steels containing around 1 per cent of manganese show a similar advantage at the lower temperatures, but that as the temperature is raised the flow-limit curve converges with that of carbon steel with a lower manganese content. In the case of 1 per cent manganese, however, the advantage is retained to a higher temperature than in the case of a 0.40 carbon steel. The two curves appear to converge somewhere between 550 and 600 deg. cent.

The figure mentioned by Dr. Jacobus as a safe working stress for carbon steels of 8000 lb. per sq. in. at 800 deg. fahr. (427 deg. cent.), which has been in practical use for a number of years, falls within the flow-limit curve which we have determined by long-time tests.

Author's Closure

The author wishes to thank those who discussed his paper for the consideration they have given it and for the valuable information submitted.

It is gratifying to note that Professor White, who is an authority on the subject, is in general accord with the working stresses given in Table 1. The work on this subject that is being done at the University of Michigan, as described by Mr. Clark, is of a most refined and exact nature and much useful information will be forthcoming.

Mr. Orrok emphasizes an important point in saying that whatever system of securing reserve strength may be selected, the question of thermal and localized stresses must be investigated and the final margin in the form of stress chosen in respect to the total calculable actual stress. He also emphasizes the importance of considering the effect of an increase in the average working temperature. As stated in the paper a variation in temperature has a great effect on the rate of creep, and in the case of any doubt it is well to err on the high rather than on the low side in assigning the working temperature.

Mr. Kanter refers to creep arrest, or what French terms a transition from "primary" to "secondary" flow, and says it is to be regretted that Professor Norton did not consider creep deceleration in his excellent series of tests. He also says that a more rational evaluation of creep data would be had if total creep over a convenient period, and inclusion of the rapid initial flow, were considered. The rate of creep determined by Professor Norton and as used in the paper is the rate after it becomes more or less uniform and does not include the effect of the initial elongation on the first application of load. It is well known that a slight amount of permanent set may occur in steel at comparatively light loads and that after a redistribution of the stresses in the steel there may be little or no permament set at the same stresses which initially caused a permanent set. This action takes place in drums and other working parts of boilers, and steel is used which has sufficient ductility to allow for a redistribution of the stresses. The most useful factor in creep tests in determining the stresses for boiler drums is therefore the rate of creep which occurs after the steel is submitted to a particular stress for a long period of time without including the initial distortion.

[19] Research Laboratory, General Electric Co., Schenectady, N. Y.

Professor Norton's, results are given in this way. For constructions other than boilers and pressure vessels the initial rate of creep may be a controlling factor, and it must not be assumed that the working stresses given in Table 1 are universally applicable.

Professor Norton refers in his discussion to additional tests he is making to determine how the rate of creep falls off with the load and whether there is any limit below which plastic flow ceases; these tests combined with others he is making will serve to throw additional light on what Mr. Kanter calls creep deceleration.

Mr. Lessells calls attention to the fact that the working stresses given are for parts where comparatively large deformation can be allowed and that there are other machine parts where the working stress must be chosen on the basis of permissible deformation. While the paper bears particularly on the selection of working stresses for drums built of A.S.M.E. Code steel having a minimum tensile strength of 55,000 lb. per sq. in., and for superheater headers of steel having a minimum tensile strength of 62,000 lb. per sq. in., the subject is considered from a broader viewpoint. As already stated, however, it must not be assumed that the working stresses in Table 1 are universally applicable."

It is interesting to note that Mr. Wood proposed a factor of safety of 1.5 based on the creep stress prior to the presentation of the paper.

Mr. Coffin states that the experiments made at the Research Laboratory of the General Electric Company show that 8000 lb. per sq. in. at 800 deg. fahr., which is given as the safe working stress in Table 1, falls within the flow limit curve determined by long-time tests, which checks the accuracy of this figure.

Mr. Howard C. Cross, of the Battelle Memorial Institute, Columbus, Ohio, called attention to an inaccuracy in Fig. 4 as published in the preliminary copy of the paper. This figure has been corrected. He also pointed out that it would have contributed to clearness if the compositions and treatments of the steel designated by code letters in Table 2 had been given. Table 4 was added to the paper to give the compositions of the steel in line with Mr. Cross' suggestion. The treatment of the steels is not given, as any close study would require further details of Professor Norton's experiments, which can be obtained from his book.

As brought out in the paper and in the discussions, there is a wide variation between different experimental results, and pending the time when there will be a closer agreement it will be well to lean toward the side of safety.

The Bin System of Pulverized Coal

By HENRY KREISINGER,[1] NEW YORK, N. Y.

The advantages of the bin system for handling pulverized coal are given as follows: Dependable feed of coal to furnace within a wide range of rating of the boiler. Easy adjustment of primary and secondary air. Coal can be pulverized in the off-peak period. Mills can always be operated at full rating. Uniform fineness of coal. Breakdown of mill does not interfere with boiler operation. Increased moisture or ash content does not affect maximum steam output of boilers. Wear on mill does not affect fineness of coal nor capacity of boiler. Clean and noiseless boiler room. High thermal efficiency of boiler plant.

IN THE bin or storage system the pulverized coal is first put through a preparation plant, from which it is conveyed to the storage bin located at the place of its use. From this storage bin the coal is fed to the furnaces and is burned as load conditions require. In the bin system the process of preparation of pulverized coal is independent of the process of burning. The difficulties that may exist in the preparation of the coal do not interfere with the process of burning. In like manner the coal may be burned with frequent changes from high to low rates without any inconvenient changes in the rate of milling.

The bin or storage system has been applied to large central stations as well as to industrial plants. One of the smallest industrial installations consists of two 320-boiler hp. boilers supplied with pulverized coal by one 6-ton roller mill. The largest central stations now burning pulverized coal use the bin or storage system. They include the plants with the highest yearly operating efficiency. The Avon Station of the Cleveland Electric Illuminating Company is operating with a yearly boiler efficiency of 88 per cent.

The bin system is also used extensively in industrial furnaces such as for heating billets and annealing. It is particularly well adapted to cases where close regulation of temperatures and furnace atmospheres is necessary.

The bin-system plants vary in design as to the location of the coal-preparation equipment. Some have a separate coal-preparation building located some distance from the boiler plant, others have the coal-preparation equipment placed near the boiler room, and in a few cases the mills are placed even in the boiler room. The location of the coal-preparation equipment depends on the plant site, the means of delivery of raw coal to the plant, and the tastes and prejudices of the designer and the operator.

The kind, the amount, and the arrangement of coal-preparation equipment vary with its location. When the coal-preparation plant is located some distance from the main plant, air transfer is generally used for conveying the pulverized coal from the preparation plant to the feeder bins in the boiler room, although the Fordson Plant has used screw conveyors about 600-ft. long for a number of years with entire satisfaction.

The use of air conveyance generally requires more equipment in the preparation plant than does the screw conveyor. There must be a complete air-compressing plant with air compressors and air-storage tanks. The coal must be dried in order that it may be transported successfully with air conveyance. This drying may require coal driers and means for removing coal dust from the drier gases before they are discharged into the atmosphere.

When the coal preparation plant is placed near or in the boiler room, the problem of preparing and conveying the pulverized coal is simplified. The air conveyance can be disposed of and the coal can be moved by short screw conveyors. The coal need not be dried to a low percentage of moisture, and in many cases the driers can be entirely omitted. What drying needs to be done can be easily accomplished in the mills during the process of pulverization.

Reason for Placing Preparation Plant at a Distance From Boiler Plant

When the coal-preparation plant is located some distance away from the main plant, it is placed at the coal-unloading plant or at the coal-storage pile. The unloading of the raw coal from railroad cars or boats or the taking of coal from the storage pile is the dustiest process around a power plant. A large amount of dust is always raised whenever the coal-unloading equipment is in operation. Therefore, wherever possible the coal-unloading equipment and the coal-storage pile are placed some distance from the main plant. The logical place for the coal-preparation plant is, then, near this coal-unloading equipment or near the coal-storage plant. The raw coal is taken directly into the coal-preparation plant, is pulverized, and then transported by air to the bins at the boilers. The transportation of pulverized coal by air conveyance is a much cleaner process than the method of conveying the raw coal from the coal-unloading equipment or storage pile to the main plant. All the dusty work is done some distance from the main plant, and the boiler room, turbine room, and switch house are kept clean and free from coal dust.

Most power plants have a coal storage in order to be assured of coal supply for power generation in case of strikes or any other cause of irregular coal shipment to the plant. Some plants receive their coal supply in large boat cargoes which must be unloaded in a specified time. Such large shipments of coal are usually unloaded into the storage coal pile, from which the coal is taken as it is required by the boiler plant. Since some methods of conveying the coal from the storage pile to the boiler plant would have to be provided, powdered coal offers a clean way of transporting this coal supply.

When the first pulverized-coal plants were designed, there was much agitation against pulverized coal, and the danger of explosion and fire hazards was much talked about. Comparatively little was known about the handling of pulverized coal and its behavior under various conditions. At that time a move was started to make rules for the safe installation and operation of pulverized-coal plants, and a separate preparation plant was at once adopted as the safest design. Little thought was given that such rules might handicap the development of the use of this new form of fuel. The designer of the plant played safe and

[1] Consulting Engineer, Combustion Engineering Corporation. Mr. Kreisinger is a graduate of the University of Illinois with the degrees of B.S. and M.E. From 1906 to 1910 Mr. Kreisinger worked with Professor Breckenridge of Yale University on fuel tests conducted by the U. S. Geological Survey. For three years he was associated with the Clinchfield Fuel Company, and then for seven years was associated with the U. S. Bureau of Mines. He has been in his present position since 1920. Mem. A.S.M.E.

Contributed by the Fuels Division and presented at the meeting, May 15, 1929, of the Boston Section, The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

placed the preparation plant some distance from the boiler room, generally at the coal-storage pile or at the coal-unloading plant.

During the last few years engineers have learned more about pulverized coal and the way to handle it. They know under what conditions it is dangerous and how to avoid such conditions. They feel that the design with the separate preparation plant far from the boiler room may entail greater expense and present many complications. They also have realized that a preparation plant can be so designed that it can be kept clean and can therefore be placed near or even in the boiler room if other considerations make such location desirable.

It would seem that a separate coal-preparation plant would make a power plant expensive. The author was once under such an impression, but closer investigation of the cost of the various types of plants designed and built within the last eight or ten years will show that such need not be the case. Once when talking with a designing engineer who was well informed on the cost of different power stations, the author expressed his opinion that separate coal-preparation plants were not a good design because they made the power plant too expensive. As examples of such designs were mentioned the Lakeside Station of the Milwaukee Electric Railway and Light Company, the Trenton Channel Plant of the Detroit Edison Company, and the Middletown Plant of the Metropolitan Edison Company. The designing engineer smiled and said this: "Do you know that the three plants you have just named are among the plants with the lowest cost per kilowatt capacity of any plants in the United States?" An examination of the cost shows that the Trenton Channel Plant costs about $103 and the Lakeside Plant and the Middletown Plant less than $90 per kilowatt capacity. Whether these low costs are due to economic design or economic construction can be determined only by careful study of the itemized cost. The high costs which appear obvious may be found not to exist on close examination. A careful, impartial study of the location of the plant, the available coal supply, the method of shipment of coal to the plant, the load factor, and the variation of the load on the plant must be made before the most economical design can be determined.

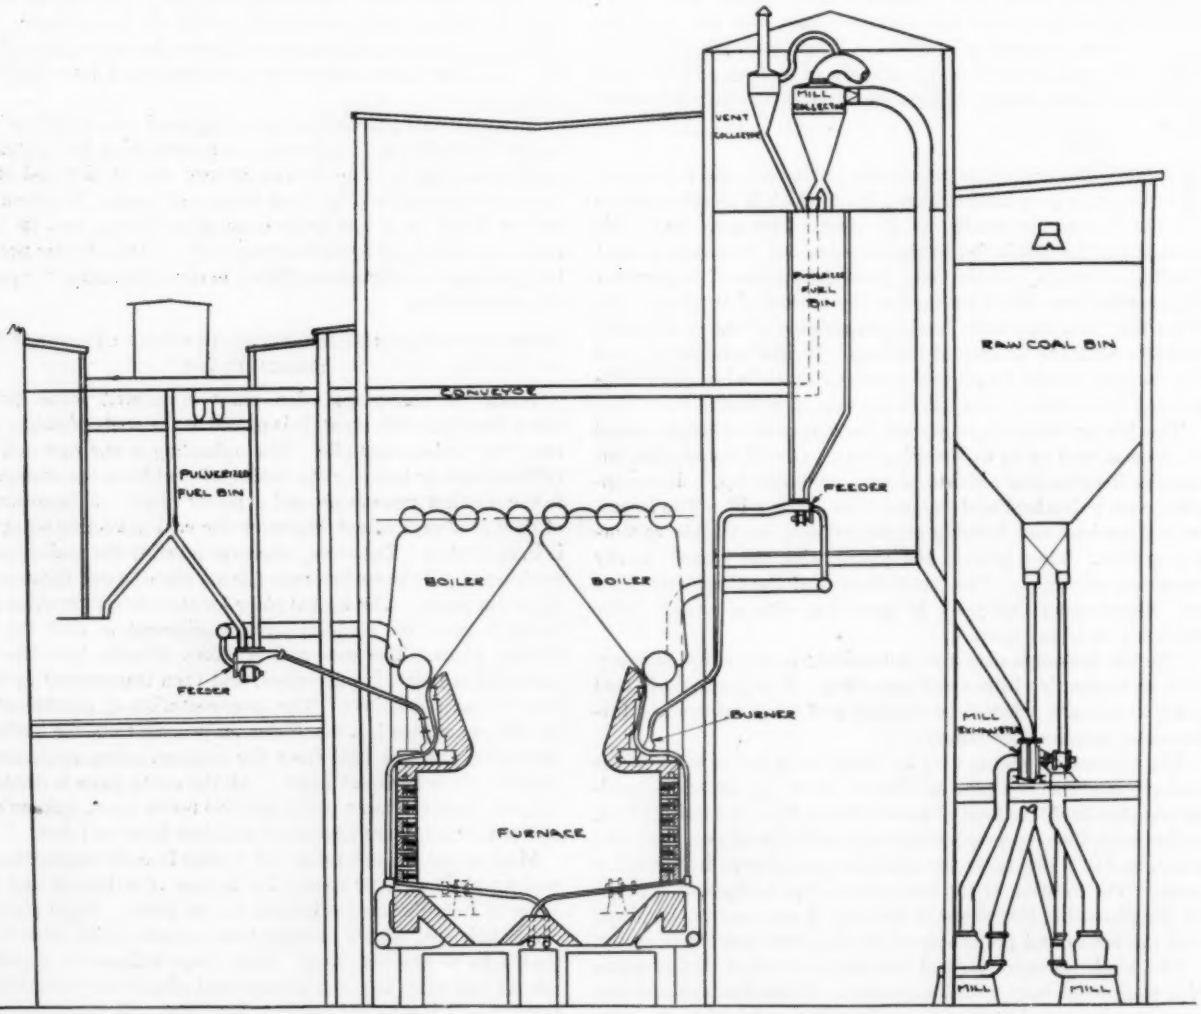

FIG. 1 LAKESHORE PLANT OF CLEVELAND ELECTRIC ILLUMINATING COMPANY
(Coal-preparation plant is located in a separate room adjacent to the boiler room.)

Fig. 1 shows the plant of the Cleveland Electric Illuminating Company. Coal-preparation equipment is located in a separate room adjacent to the boiler room. Screw conveyors are used to convey pulverized coal to the feeder bins.

Fig. 2 shows the plant of the United Railways Company, Providence, R. I. The mills are on a platform in front of the boilers.

Sequence of Processes in the Bin System

The following is the sequence of processes in the bin or the storage system:

(*a*) Drying raw coal
(*b*) Pulverizing coal
(*c*) Transporting pulverized coal to feeder bins
(*d*) Feeding pulverized coal to burners
(*e*) Burning pulverized coal.

Drying

Ten years ago it was thought necessary to dry all coals below 1 per cent moisture in order that the coal could be successfully pulverized and burned. Separately fired horizontal rotary driers of the kiln type were then in general use. As experience in preparing and burning pulverized coal accumulated, it became evident that such extreme drying of coal is needed only in very few cases. In most cases the moisture in the dried coal may be considerably higher. Inasmuch as the separately fired horizontal driers were costly to install and to operate, and took too much space, the possibility of using successfully coals with higher percentages of moisture introduced other types of driers which were more compact and did not require separate firing. Thus flue gas and steam driers with gravity feed were made use of, and later a vertical rotary drier heated with steam was developed.

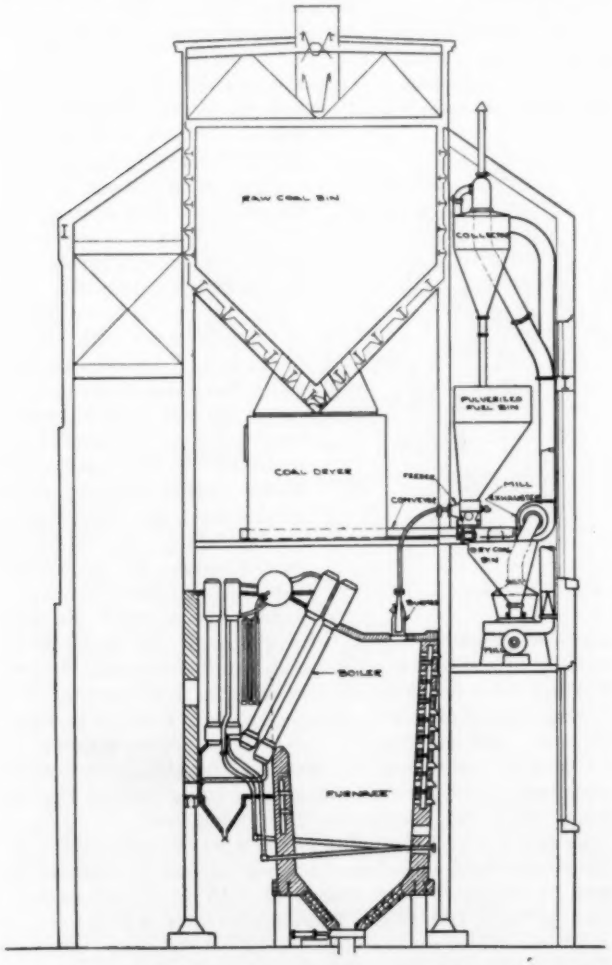

Fig. 2 Plant of United Railways Company, Providence, R. I. (Mills are located in the boiler room in front of the boilers.)

Still more recently drying coal in mills was applied with considerable success, and many of the new powdered-coal plants are installed with this method of drying.

Gravity-Feed Driers. The gravity-feed-type driers did not come up to full expectations, and very few are now being installed. The chief objection against them is that the gravity feed is not reliable; the coal hangs in them and does not flow through them at a uniform rate. When the coal is very wet and fine, the flow may stop altogether. Thus the drier is least effective when most needed.

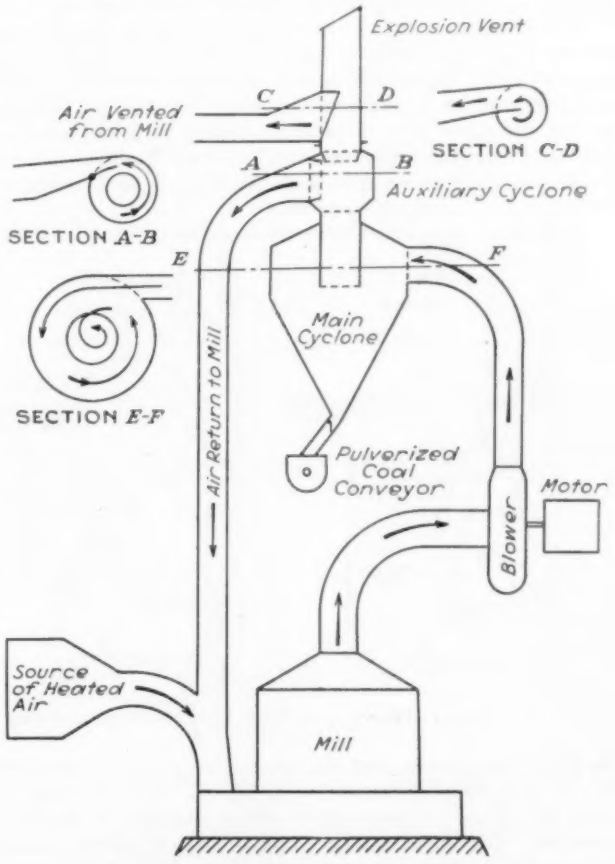

Fig. 3 Mill System Arranged for Drying

Vertical Rotary Steam Drier. The rotary steam drier gives the coal a positive flow, and therefore the drier is very useful for very fine and wet coals which need drying the most. The vertical rotary steam drier takes very little floor space, but requires considerable head room. It is probably the best drier for power-plant purposes.

Dust Emission From Driers. All driers emit a certain amount of dust with the air or gas which is used in drying. The horizontal rotary drier is the worst offender in this respect because the coal cascades in the drier, and much dust is thereby put in suspension in the gases and carried out. It is necessary that the air or gas from the driers be sent through a cyclone separator to remove most of the dust, and in some cases the gas or air must be washed before it is discharged into the atmosphere.

Mill Drying. The mill drying has much to recommend it. It is capable of doing as much drying as is necessary, with very little additional apparatus. Fig. 3 shows diagrammatically the mill system arranged for drying. In the air-separation mill 2 to 3 lb. of air per pound of coal are circulated through the mill system to lift the pulverized coal out of the mill and deposit it

in the cyclone separator. When coal is dried in the mill, heated air is continually introduced into the mill system and an equal weight of air taken out of it. The added air supplies the heat needed for drying, and the air vented from the mill carries away the moisture that has been driven from the coal. For drying purposes $^1/_2$ to $1^1/_2$ lb. of heated air per pound of coal is supplied. By the mill-drying method 2 to 6 per cent of moisture can be removed from the coal. The heated air for drying can be supplied from the air heaters for heating air for combustion with the flue gases or it can be supplied with a special steam air heater located near the mill and heating the air with high-pressure steam.

If the mills are located near the boiler room, the air vented from the mill can be used either as primary or secondary air, or otherwise blown into the furnace, so that the dust which it may carry can be burned, and no special devices are required for cleaning the air. In cases where the mills are located far from the boiler room and it is impractical to carry the vents from the mill to the furnaces, it is necessary to wash this air in air washers before discharging it into the atmosphere.

Air Washer. In the air washer the dusty air is first humidified by low-pressure steam, and the mixture of steam and dusty air is then subjected to very fine water sprays. The water sprays cool the mixture and cause the steam to condense on the dust particles. The condensation of steam on the dust particles causes them to become heavy and more easily thrown out of suspension. The wetted and coagulated dust particles are collected in the hopper-shaped chamber in which the air makes a turn of 180 deg. In order to facilitate the settling of the wetted particles, eliminators in the form of vanes are placed in the stream of the gas at the point of turning. Water sprays are used to keep the eliminators free of dust.

The amount of dust carried from the mill into the air washer depends upon the volume of the air used for drying and the percentage of moisture to which the coal is reduced by the drying process. The larger the volume of air vented from the mill, the greater the quantity of dust carried into the air washer. Also the lower the percentage of moisture in the dried coal, the greater the dust loss. If the percentage of moisture in the dried coal is to be low, the humidity of the air passing through the mill must be low in order that the moisture would leave the coal and be absorbed by the air. On the average the dust lost in the air washer is about 0.5 per cent.

Disposal of Mill Vents. Fig. 4 shows the method of disposing of the mill vents without an air washer. The mill vents are used as primary or as secondary air, or a combination of the two. The diagram on the left of the figure shows the mill vent used as part of the secondary air introduced directly into the horizontal burner. The diagram on the right shows the mill vents used as secondary air with vertical firing, in which case the mill vent is blown into the furnace through air ports in the front wall. The diagram in the middle shows the mill vents used as a combination of primary and secondary air. Such use of the mill vents is practicable only when the mills are located near the boiler room so that the ducts need not be excessively long.

Location of Cyclone Separator. The cyclone separator can be under either pressure or suction. In the older installations the cyclone separator was always under a pressure. That is, the mill blower was located at the outlet from the mill and forced the mixture of coal into the cyclone. With such arrangement the mill blower handled all the coal, and there was a considerable abrasion of the mill blower due to the high concentration of dust. The blades of the blower wheel suffered especially from such abrasion and had to be renewed after the mill had pulverized 10,000 to 30,000 tons of coal.

In order to eliminate this abrasion, the mill blower in more recent installations is located between the cyclone separator and the mill. The mill blower then handles the air after the coal dust has been separated out of it by the cyclone. With such an arrangement there is practically no wear on the mill blower, and the blades last indefinitely.

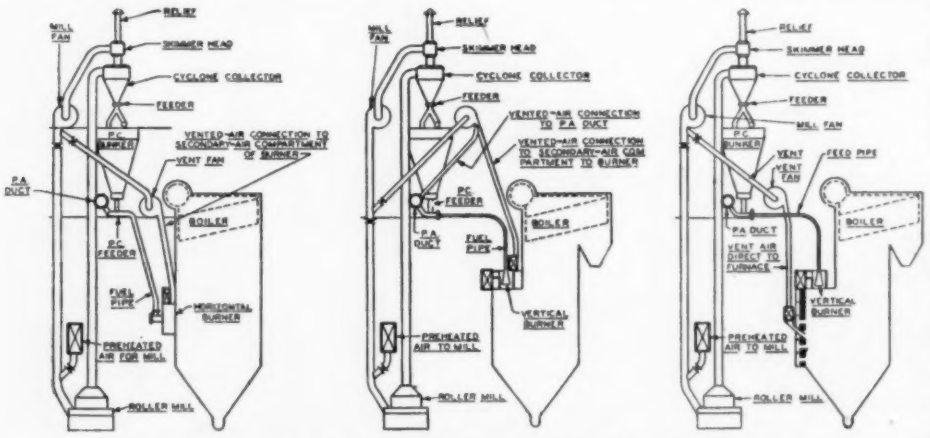

FIG. 4 DISPOSAL OF MILL VENTS BY UTILIZING THE AIR FOR COMBUSTION

Fig. 5 shows the two locations of the mill blower with respect to the cyclone separator and the mill. The diagram on the left shows the mill blower located between the mill and the cyclone separator. In this case the mill blower handles the mixture of air and coal dust. The diagram on the right shows the blower located between the cyclone and the mill. The mill blower handles the air after the dust has been separated from it. In both cases the heated air is supplied by a special small steam air heater located near the mill. The mill vents are shown to discharge into an air washer.

Percentage of Moisture. The percentage of moisture to which the coal must be dried for successful operation depends on the kind of coal. Generally speaking, the high-grade Eastern coals must have a lower percentage of moisture than the Western coals. Thus the Pocahontas, New River, and Pennsylvania coals may require drying down to 2 or 3 per cent of moisture, the Illinois and Iowa coals down to 6 or 8 per cent of moisture, the semi-bituminous Western coals to 12 or 15 per cent of moisture, and the North Dakota and Texas lignites to 24 or 28 per cent of moisture. There are two large central stations using pulverized lignite where the lignite is dried in gravity-feed steam driers to an average of about 26 per cent moisture. With this apparently high moisture the lignite pulverizes, handles, and burns satisfactorily. In both of these plants the pulverized lignite is conveyed to the feeder bin by screw conveyors.

PULVERIZATION OF COAL

The fineness to which coal must be pulverized in order to be successfully burned varies with the kind of coal. Generally speaking, the high-fixed-carbon coal must be pulverized to a higher degree of fineness than the high-volatile-matter coals. The volatile matter leaves the particles of coal upon heating and burns largely as gas. It is therefore easy to burn. The fixed carbon,

however, stays as coke residue in the coal particle and burns slowly. The smaller the original coal particle, the smaller will be the coke residue of the fixed carbon and the less time will be required to burn it completely. If the original coal particles are large, the coke residue left after the distillation of the volatile matter may be too large to burn completely while they remain in the furnace. The high-fixed-carbon Eastern coals should therefore be pulverized to a fineness of 65 to 75 per cent through a 200-mesh screen, the high-volatile coal to a fineness of 55 to 65 per cent through a 200-mesh screen, and the lignites and peats to 40 to 50 per cent through a 200-mesh screen. On the other hand, the anthracite coal may have to be pulverized to 80 or 85 per cent through a 200-mesh screen to get equally as good combustion as with the other coals.

The degree of fineness should also vary according to the furnace in which it is to be burned. If the furnace is small, the coal must be pulverized very fine in order that complete combustion may be obtained. In the same way a large furnace will burn fairly coarse coal without high losses from incomplete combustion.

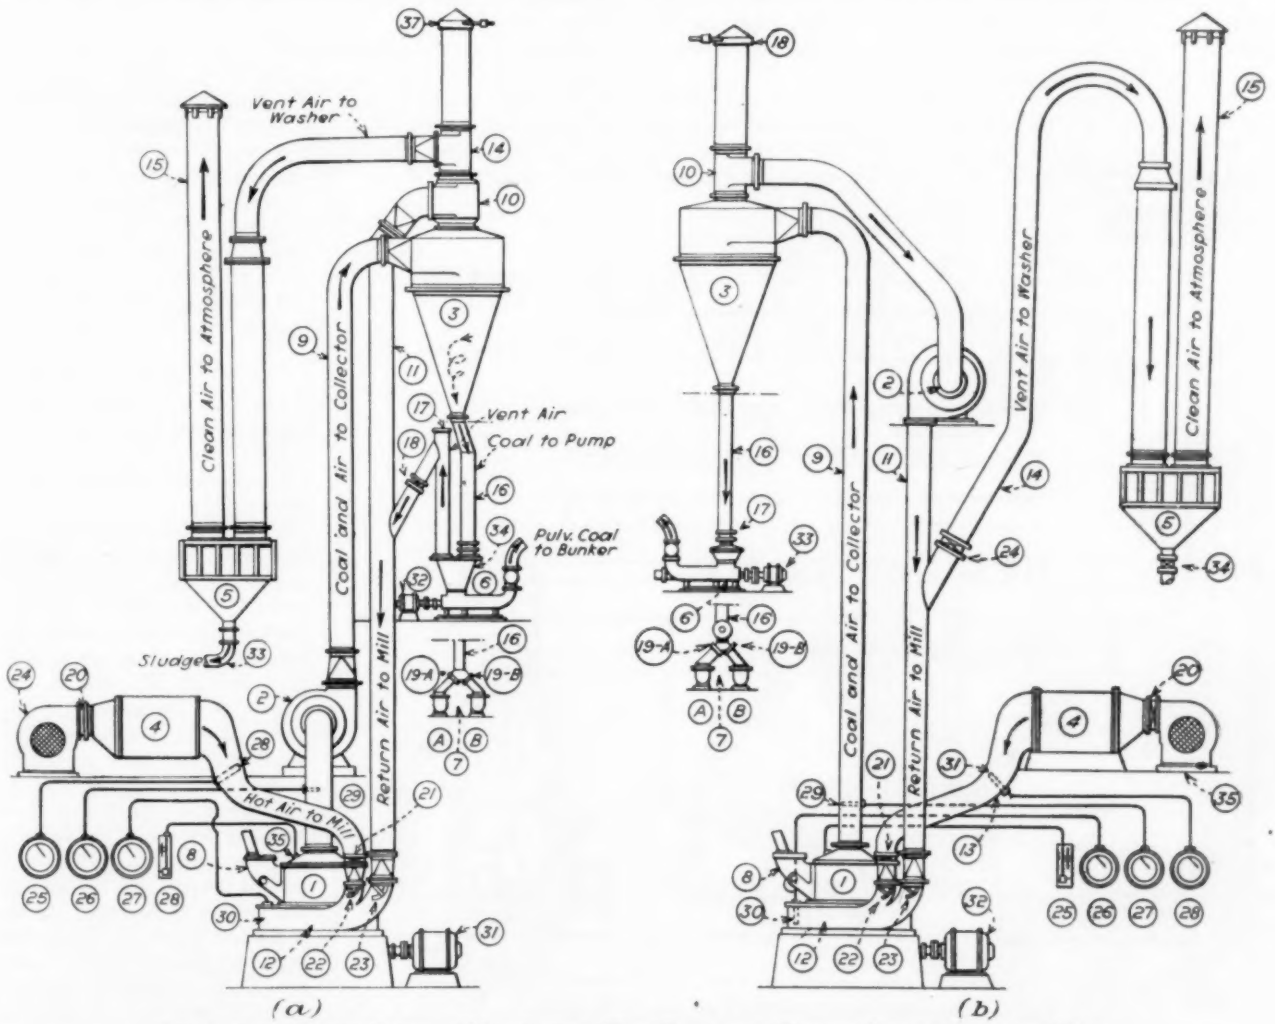

FIG. 5 TWO WAYS OF LOCATING MILL BLOWER WITH RESPECT TO CYCLONE SEPARATOR AND THE MILL

(The diagram on the left shows the mill blower between the mill and the cyclone separator; the blower handles pulverized coal. The diagram on the right shows the mill blower between the cyclone and the mill; the mill blower handles the air after the pulverized coal has been separated from it.)

TRANSPORTATION OF PULVERIZED COAL

The pulverized coal is transported either by screw conveyors or air conveyance. The screw conveyors are cheaper to install and to operate. They are simple in construction and reliable in their operation. If the distance over which the coal is to be conveyed is not too long, the screw conveyor generally proves the more satisfactory means of moving pulverized coal.

Air conveyors are used in practically all cases where the preparation plant is located some distance from the boiler room. They lend themselves easily to central control of the distribution of coal.

That is, coal can be delivered to any bin in the boiler room by means of electrically operated valves which can be opened or closed from a centrally located switchboard. Several air conveyors can feed one main line, and the coal can be discharged to any bunker in the boiler room. Fig. 6 is a diagram of a coal-distribution system by air conveyance. The amount of air and the pressure required for the transportation of powdered coal vary with the distance, and generally 20 to 60 lb. of coal can be transported with 1 lb. of air. The pressure at the transporter varies from 20 to 60 lb. per sq. in., depending on the length of the transport line and the number of turns in it. The velocity of the mixture of coal and air through the transport line is about 20 ft. per sec.

Feeding of Pulverized Coal

The pulverized coal is fed from the storage or feeder bins to the furnaces at any desirable rate by means of feeders. Fig. 7 shows four representative types of feeders. Of the four types the two with the vertical shafts shown at the top of the figure give the most satisfactory all-around results. These feeders have agitators attached to the top end of the vertical shaft which prevent bridging of the coal and cause it to flow without interruption into the feeder. The feeder at the right is a duplex feeder; that is, it feeds two streams of coal of equal size and therefore can supply two burners with coal.

The lower half of the figure shows two screw feeders. The one on the right is a single-screw feeder and is one of the oldest devices for feeding pulverized coal. If the coal is very dry the coal may flood through the screw and cause irregular feedings.

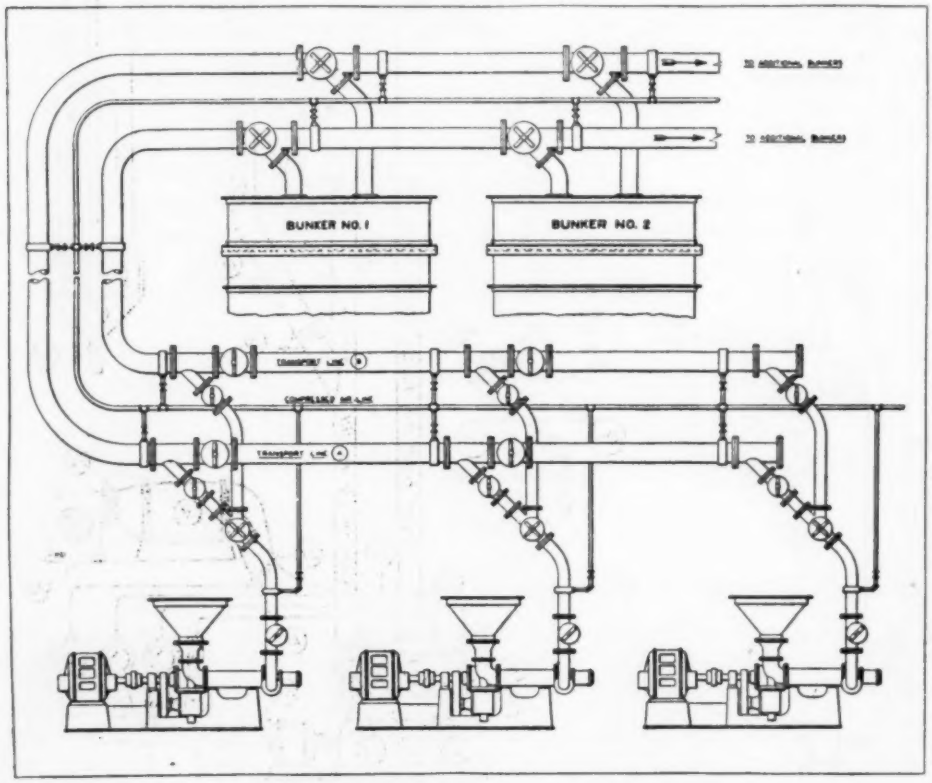

Fig. 6 Coal-Distribution System by Air Conveyance

In order to stop this flooding a special check valve is placed at the discharge end of the feeder screw. This check valve consists of a disk which is gently pressed by a helical spring against the barrel of the feeder. The check valve keeps the barrel of the feeder full of coal and allows the coal to pass only as fast as the feeder screw moves it. The flooding does not exert sufficient pressure on the check valve to open it and permit the coal to go by. A rotary agitator is placed above the feeder screw to stir the coal, thus making it flow into the feeder screw. There are a great many of these feeder screws in operation, and in many cases they are entirely satisfactory. In fact, some of the users are reluctant to change to the newer types of feeders. In other cases considerable difficulty is encountered with the coal sticking in the feeder and causing irregular feeding and excessive wear on the screw.

The picture at the lower left-hand corner shows a double-screw feeder. The double-screw feature is intended to eliminate flooding. Observations on this type of feeder show that in this respect the feeder is successful.

Rate of Feeding. The rate of feeding the coal is determined by the speed of the feeder. The feeders are driven either by variable-speed motors or by constant-speed motors through a variable-speed drive. In general, the variable-speed motor is more desirable. It takes less space, and the control of the feeding is more easily obtained. It is also more reliable, and the maintenance is low.

Usually the variation in speed in the ratio of 1 to 4 is employed. Generally, there is more than one feeder on a boiler, so that by shutting down some of the feeders a further reduction in the rate of feeding can be obtained. This is one of the advantages of the storage system and permits very wide variation in the rate of working the boiler. In one installation a ratio as high as 1 to 12 in the rate of feeding coal is used with good combustion results. The power required to drive the feeders is about one-half of a horsepower per ton of coal per hour.

Firing Pulverized Coal

There are three ways of firing pulverized coal in general use—namely, the vertical firing, the horizontal firing, and the tangential firing.

Vertical Firing. In the vertical-firing method the mixture of coal and primary air is fired vertically downward through burners located in the arch of the furnace. Secondary air is supplied through air ports in the front wall. The mixture of primary air and of coal and the secondary air meet at right-angles, thus producing mixing. The stream of coal and air turns near the bottom of the furnace and flows upward, making the path of the coal and air through the furnace of U-shape. In installations where air heaters are used, the secondary air is preheated and supplied to the furnace under a pressure varying from about 1 to 2 in. of water. When the secondary air is supplied under pressure, the air ports in the front wall are small and the air enters the furnace with high velocity, and more turbulent mixing is produced.

The rate of combustion is usually limited by the ability of the furnace walls to withstand the slagging action of the ash. With refractory walls the rate of heat liberation is 10,000 to 18,000 B.t.u. per cubic foot of combustion space per hour. With water-cooled furnaces the rate of heat liberation is often 25,000 B.t.u. per cubic foot of total combustion space per hour. With water-cooled furnaces the limit to the rate of heat liberation is the slagging of the boiler tubes. If the rate of heat liberation is too high, molten ash is carried into the boiler tubes and clogs the gas passages.

Horizontal Firing. In the horizontal method of firing the secondary air is usually supplied under pressure. This is particularly true where air heaters are used. The secondary air, as well as the primary air is given a rotative motion as it leaves

the burner, which motion produces very turbulent mixing, resulting in good combustion.

Tangential Firing. In the tangential method of firing the burners are located in the corners of a nearly square furnace. The streams of mixture of coal and air are directed toward the center, tangent to a small circle. The burners are located either near the top of the furnace, with the gases moving in the general downward direction, or at the bottom of the furnace, in which case the gases are moving in a general upward direction. The impingement of the four streams of coal and air against each other near the center of the furnace produces very intensive mixing, and combustion takes place at very high rates. Inasmuch as there is also considerable impingement of the flame against the side walls, this method of firing is used only with water-cooled furnaces. The usual rate of heat liberation is 20,000 to 30,000 B.t.u. per cubic foot of total furnace volume.

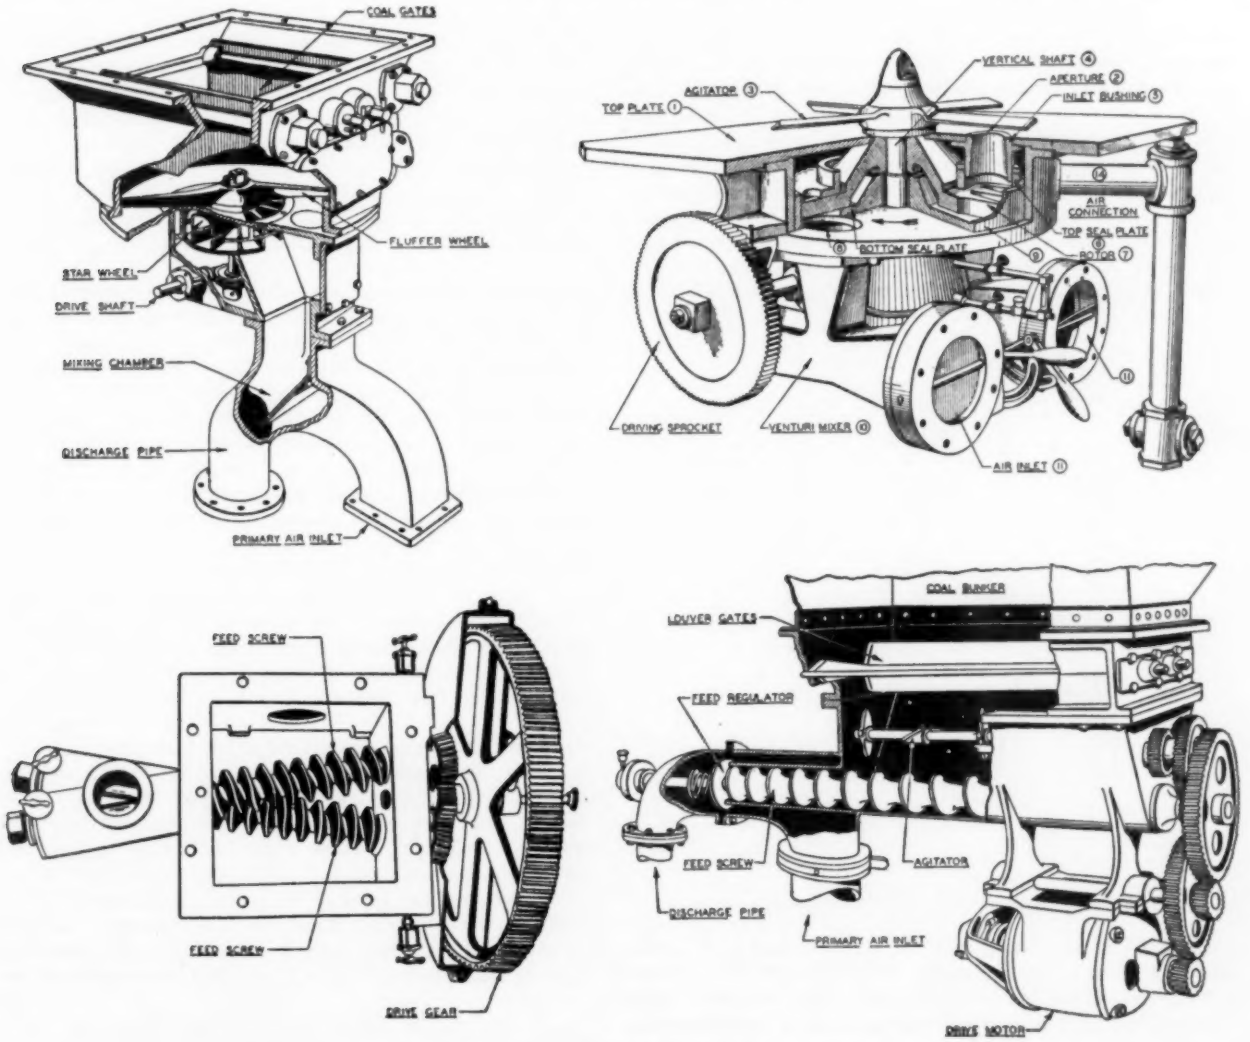

FIG. 7 FOUR TYPES OF PULVERIZED-COAL FEEDERS

These features make the bin system especially desirable for a power plant supplying power to railroads where the load varies over a very wide range and for steel plants where pulverized coal is burned as a supplementary fuel to blast-furnace gas.

In one railroad plant the load on the turbo-generator is increased from 5000 to 20,000 kw. within one minute and is frequently dropped within the same short time. The boilers must be able to pick up the load without appreciable steam-pressure drop and must drop it without the blowing off of the safety valves.

At the plant of the Youngstown Sheet and Tube Company powdered coal is used as auxiliary fuel to blast-furnace gas. Whenever the gas supply is reduced below the quantity necessary to hold the pressure at a given point, coal feeders and burners are automatically turned on and kept in operation, holding the pressure constant until the blast-furnace gas supply is increased, when the feeders and burners are again automatically turned off.

(3) Coal can be pulverized in the off-peak period, making it possible for the plant to generate more salable power during the peak-load periods. Thus the storage plant has higher peak capacity, which, when capitalized, reduces the first cost of the station.

ADVANTAGES OF THE BIN SYSTEM

(1) Uniform and dependable feed of coal to furnace within a wide range of rating of the boiler.

(2) Easy adjustment of primary and secondary air to any coal and rate of feeding.

(4) Mills can be always operated at full rating, which gives the lowest power consumption per ton of coal pulverized.

(5) Uniform fineness of coal.

(6) Breakdown of a mill does not interfere with the boiler operation.

(7) Increased moisture or ash content of the coal, though it may affect the rate of milling, does not affect the maximum steam output of the boilers.

(8) Wear on the mill does not affect the fineness of coal and the capacity of the boiler.

(9) Clean and noiseless boiler room.

(10) High thermal efficiency of boiler plant.

FSP-52-37

The Purpose and Characteristics of the Air-Flow Mechanism of a Boiler Meter

By W. G. LAUFFER,[1] NEW YORK, N. Y.

Stack loss in a modern steam-generating station is assumed to be a controllable item effected by the installation and use of combustion guides. The paper reveals the probability of error in such an assumption. The air-flow mechanism of a well-known boiler meter, the proper operation and calibration of which have probably not been understood, is given a detailed study in this report, and the result is described as resulting in an indicator of combustion efficiency that is reliable within close limits.

THE largest controllable loss in a modern steam-generating station is the stack loss. In the design of a station, it is usually assumed that control of the stack loss will be satisfactorily effected by the installation and use of combustion guides. This report reveals the probability of error in such an assumption. The air-flow mechanism of a well-known boiler meter is used at the Hudson Avenue Station for control and indication of the stack loss. The proper operation and calibration of this meter had not apparently been properly understood nor completely developed. However, the detailed study of the purpose and characteristics of the mechanism, which is described in this report, has resulted in an indicator of combustion efficiency that is reliable within very close limits.

Excepting a brief description of the meter, included for clarity and completeness, only the additional developments of the theory and use of the air-flow mechanism are here discussed. Detailed description has been left to the manufacturer's bulletins and instructions.

The work was conducted by the Hudson Avenue Station betterment crew of the Test Bureau, Operating Department, Brooklyn Edison Company. The author wishes to express his recognition of the spirit in which was carried out the routine of innumerable Orsat analyses and "deadweight checks," on which rests the proof of the theories presented. Indebtedness is also acknowledged to the engineers directly in charge of the operation of the station as a whole, and of the boiler room in particular, who, appreciating the importance of the problem, rendered every possible assistance to arrive at a satisfactory and prompt solution.

The report of the work is divided into four parts:

Part I relates the difficulties that had been encountered in setting the boiler meters for predetermined air requirements and the first steps that were taken to remedy these difficulties. This part also describes the development of a method of calibrating the meter against differential, the "deadweight check," and presents the computations involved.

Part II includes the fundamental mathematics for the derivation of the proper displacer contour. This is expanded in the Appendix.

Part III is a discussion of the determination of the desired characteristic of total air with respect to rating. This part also includes the development of the proper technique of flue-gas sampling and the demonstration of the necessity for gas-sampling lines on both sides of the boilers.

Part IV describes in detail the routine that has been developed to insure continuous maintenance in calibration of the air-flow mechanism, the necessity of which is a fundamental prerequisite to a consistently minimum stack loss.

The text has been written with the technical theme interwoven with the actual progression of the practical work involved in the determination of the correct functioning and use of the instrument. It is believed that this treatment is not only most interesting, but will awaken an appreciation of some of the basic reasons why the application of instrument guides for combustion have been only too commonly discounted by the men who use them.

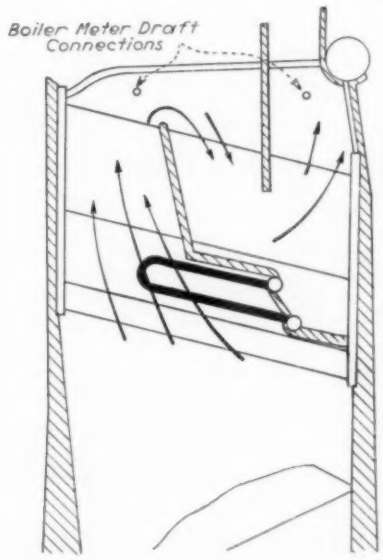

FIG. 1 POINTS AT WHICH DRAFT IS TAPPED OFF

DESCRIPTION OF THE BOILER-METER MECHANISM

The boiler-meter-flow elements in question measure the flow of steam from the boiler and the flow of products of combustion through the boiler. The air-flow pen is to be so adjusted that, when the fuel is being burned with the proper amount of air, the two pens, indicating air flow and steam flow, show the same reading on the boiler-meter chart.

The steam-flow element consists of a bell actuated by the difference in pressure occurring just before and immediately after an orifice or flow nozzle in the steam line from the superheater outlet to the header. This bell is so shaped that the movement is proportional to the square root of the actuating differential, and consequently directly proportional to the flow causing the differential.

The air-flow element measures the flow of flue gas through the

Presented at a meeting, New York, N. Y., May 9, 1929, of the Metropolitan Section of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

boiler and is actuated by the differential draft between two points in the boiler in the gas path. The boilers at the Hudson Avenue Station are of the B. & W. cross-drum three-pass type. The points at which the draft is tapped off are at the top of the first pass and at the top of the third pass. (See Fig. 1.) The difference in draft between these two points represents a friction loss of head due to the gas flow through the boiler. This head loss has the characteristic of all friction-head losses—i.e., the loss is proportional to the square of the flow. Since, however, in this meter the steam and air pens are to be coincident, the air-flow element must, like the steam-flow element, give a deflection that is proportional to the flow rather than one proportional to the square of the flow or to the head. This is accomplished by counterweighting the arm from which the draft-actuated bells hang with a weight which is immersed in mercury. This weight or displacer is so shaped that, in withdrawing it from the mercury, the force exerted by it on the arm will cause the meter reading to be proportional to the air flow.

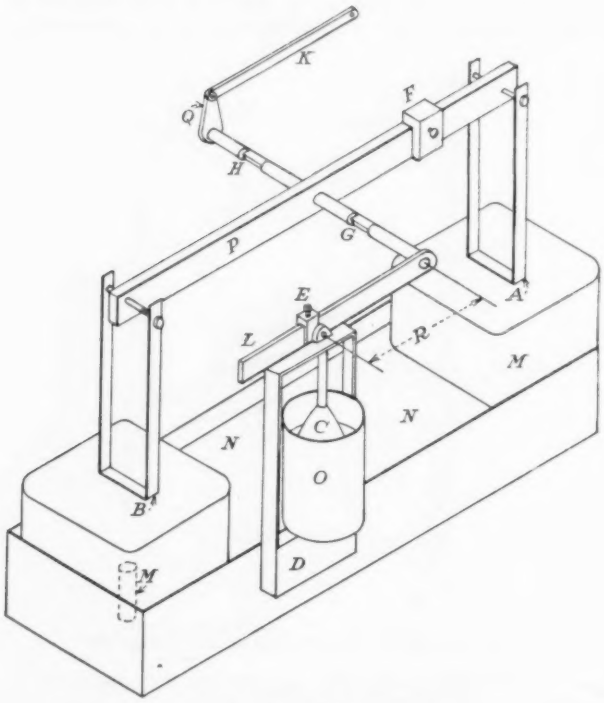

FIG. 2 AIR-FLOW MECHANISM

The air-flow mechanism is shown in Fig. 2. *A* and *B* are the draft bells suspended in a bath of oil *N*. The draft is introduced under the bells through the $^1/_8$-in. pipes *M*. *C* is the displacer, fixed in its yoke weight *D*, hanging in the cup of mercury *O*, from the movable clamp *E*. The air bells, the displacer, and its yoke weight all act on the lever *P*, which, balanced on the knife edges *G* and *H*, operates the air pen through crank *Q* and arm *K*. The weight *F* is an additional adjustment, the function of which is explained later in detail. The meter is set for any desired excess air at a given boiler rating by changing the distance of the clamp *E* from the fulcrum—i.e., by changing the distance *R*. This distance is hereafter referred to as the "radius" of the meter, while the weight *F* is referred to as the "counterweight" or "balance."

When the meter is installed, the higher draft (in this case the draft at the top of the third pass) is introduced under bell *A* and the lower draft under bell *B*. When the beams *P*, and consequently *L*, are in zero position against a stop which is not shown in the sketch, the mercury in the pot *O* is carried at the level of the joint between the displacer and the rod from which it hangs. The zero position is assumed by the mechanism when there is no differential between the bells *A* and *B*.

As the difference in draft between bells *A* and *B* increases, a torque is exerted in a clockwise direction. This tilts the arm *P*, lifting the displacer *C* out of the mercury. The downward force exerted on the lever *L* by the displacer and its yoke is thus increased, since the buoyant effect of the displaced mercury is being decreased. The turning of *P* continues until a state of equilibrium is reached. Thus, for any given radius setting and counterweight position, there is a definite relation between the displacement of the arm *P*, and consequently the pen reading, and the actuating differential.

PART I THE USE OF THE DEADWEIGHT CHECK

Analysis of the flue gases by Orsat is the basis on which the meter adjustments are checked, and considerable difficulty had been experienced in obtaining reliable and consistent checks. When the radius was set according to the results of Orsat analyses at one rating, it was usually found that it was impossible to check the desired excess air at other ratings. This inconsistency was ascribed to almost every possible and impossible cause, among the principal ones being that the changing effect of chimney action in the second and third passes of the boiler made accurate setting impossible and that difference in fuel-bed condition caused decided differences in the differential draft for the same air supplied. It has been found that neither of these has any discernible effect on the accuracy of the meter when it is properly adjusted.

As a possible solution it was suggested that the meter be calibrated against draft directly, on the chance that the meter might not be indicating properly the rating corresponding to a given draft differential. This was to be accomplished by connecting a liquid-level draft gage in parallel with the air bells of the meter. At this time it was erroneously believed that, in general, the problem of the proper application of the meters had already been completely solved; the calibration of the meters against draft was to detect slight inconsistencies caused by the possibility of dirt or excessive friction in the meter.

Simultaneous gas analyses and draft differentials with coincident pen readings were found to be rather confusing. While individual Orsat checks were shown to be correct or incorrect, as the case might be, an inconsistent function of draft against rating was indicated, showing a minimum draft point at about 125 per cent of rating. As the rating decreased below 125 per cent, the differential draft increased. If this were a true indication of the calibration of the meters, they would be practically valueless below 150 per cent of rating. Such was probably the case for the condition in which the meters then were. However, there was so much uncertainty concerning the accuracy of the draft readings that this method was discarded in favor of the "deadweight check."

The "deadweight check" applies a method of computation, which later developments proved invaluable, by means of which the shape of the total air characteristic can be calculated for a series of rating points if the differential drafts at these ratings are known. This method assumes that, first, the resistance of the boiler as a conduit is constant for a given condition of cleanliness and that therefore the friction loss through it (in this case the differential draft between first and third passes) is exactly proportional to the square of the flow, and, second, that the actual evaporation per pound of coal is constant within the limits imposed by the accuracy of the measurements.

If, then, the differential drafts at any two ratings are known, the respective rates of air flow are proportional to the square

roots of the differentials. Also, if the coal burned is proportional to the rating, the quantity of air theoretically required for combustion is proportional to the rating, and the air flow is then proportional to the product of rating and per cent total air. (The term, per cent total air, as used in this report, is the ratio of the quantity of air actually supplied to the boiler to that theoretically required for combustion, expressed in per cent; or, in other words, it is 100 per cent plus the per cent excess air.) There are therefore two expressions—square root of differential, and product of rating and per cent total air, both proportional to the same quantity, air flow. If the change in one is known, the change in the other may be determined. Thus, for example, suppose that an Orsat analysis has shown that at 200 per cent of rating the total air is 116 per cent and the differential draft at this rating is 0.690 in. of water. If the differential at 90 per cent of rating is 0.154 in. of water, what is the per cent total air at 90 per cent of rating?

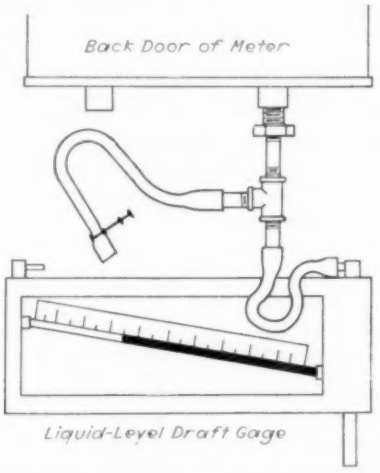

FIG. 3 MECHANISM FOR CALIBRATING AIR FLOW

Let F_1 = air flow at 200 per cent of rating
F_2 = air flow at 90 per cent of rating
$F_1 = 200 \times 116 = 232$

Now

$$\frac{F_2}{F_1} = \frac{\sqrt{0.154}}{\sqrt{0.690}}$$

So

$$\frac{F_2}{232} = \frac{\sqrt{0.154}}{\sqrt{0.690}}$$

$$F_2 = \frac{\sqrt{0.154}}{\sqrt{0.690}} \times 232 = 110$$

F_2 = 90 × per cent total air = 110

Therefore, per cent total air = 110/90 = 122 per cent at 90 per cent of rating.

Calibration of the air-flow mechanism by means of the method just outlined was then undertaken. This was accomplished by disconnecting the lines from the boiler, applying an artificial differential which is measured by a draft gage in parallel with the mechanism, and calculating the total air characteristic from the "deadweight check." The arrangement of the apparatus for this is shown in Fig. 3. The regular draft connections to the two nipples at the back of the meter are removed. The left-hand nipple, introducing draft under bell *B*, Fig. 2, is left open to atmosphere. The pipe fittings shown are connected to the right-hand nipple, which introduces draft under bell *A*, Fig. 2. In order to apply the artificial differential when checking the meter, air is sucked out through the rubber tube equipped with a pinch cock, thus creating the same suction under bell *A* and on the inclined draft gage. The air-pen reading and the corresponding draft-gage reading are recorded. (Instead of the temporary connections shown in Fig. 3, the draft gage may be permanently connected to the meter and the piping so arranged that it is not necessary to disconnect the meter, but only to remove two plugs and close two valves in order to obtain the simultaneous draft and pen readings.)

It is possible to obtain these draft and rating readings over the entire range of the meter in an hour or less. These readings may be plotted and the total air characteristic derived. If the characteristic is found to be incorrect, the trouble can be quickly diagnosed and the necessary steps taken to correct it. It may be well to remark here that the accuracy of the assumptions on which this method is based was verified by checking the characteristic by Orsat analysis. These data will be presented later.

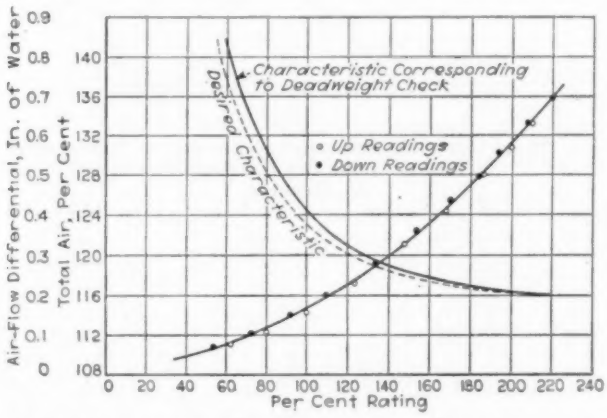

FIG. 4 DEADWEIGHT CHECK AND TOTAL AIR CHARACTERISTICS

A typical "deadweight check" is given in Table 1 as an example.

TABLE 1 TYPICAL DEADWEIGHT CHECK

BOILER METER NO.... PEN READING VS. DIFFERENTIAL DRAFT

Up		Down	
Air-pen reading	Draft-gage reading	Air-pen reading	Draft-gage reading
54	0.070	...	...
72	0.103	62	0.074
92	0.150	80	0.110
110	0.200	100	0.160
134	0.280	124	0.230
154	0.360	148	0.325
170	0.435	168	0.410
184	0.494	186	0.500
194	0.555	200	0.570
208	0.630	210	0.630
220	0.690	...	...

These readings are plotted in Fig. 4. The computation of the total air characteristic is given in Table 2 and is shown by the solid line in Fig. 4. The dotted line shows the desired characteristic.

These data show the characteristic to be a little too steep; that is, it is too high at the low ratings. (See Fig. 4.) The remedy is to move the counterweight *F* in Fig. 2 to the right—that is, to balance the meter slightly lighter at zero. If the value of total air as indicated by the deadweight were found to be too low at the low ratings—that is, less than 120 per cent at 120 per cent of rating—it would be necessary to weight the meter heavier at zero by moving the counterweight *F* to the left. It has been found possible to obtain a wide range of characteristics

TABLE 2 COMPUTATION OF TOTAL AIR CHARACTERISTIC ON THE BASIS OF DEADWEIGHT CHECK

Per cent rating[a]	Differential draft across airbells a	Differential in per cent of that at 200 per cent of rating	Per cent flow; square root of per cent differential	Flow in arbitrary units; product of per cent rating and per cent total air[b]	Per cent total air[a]
220	0.690	119.58	109.35	254.3	115.6
200	0.577	100.00	100.00	232.6	116.3
180	0.473	81.98	90.54	210.6	117.0
160	0.380	65.86	81.15	188.8	118.0
140	0.297	51.47	71.74	166.9	119.2

[a] See Fig. 4.
[b] 116.3 per cent is the desired total air at 200 per cent of rating.
$116.3 \times 200/100 = 232.6$.

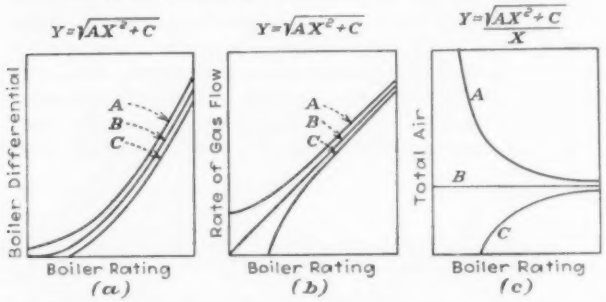

FIG. 5 THREE CURVES OF DIFFERENTIAL OBTAINED BY DEADWEIGHT CHECKS, WITH CORRESPONDING GAS FLOW AND PER CENT TOTAL AIR CURVES
(In the equation $Y = Ax^2 + C$, for $A, C = +K$; for $B, C = 0$; for $C, C = -K$.)

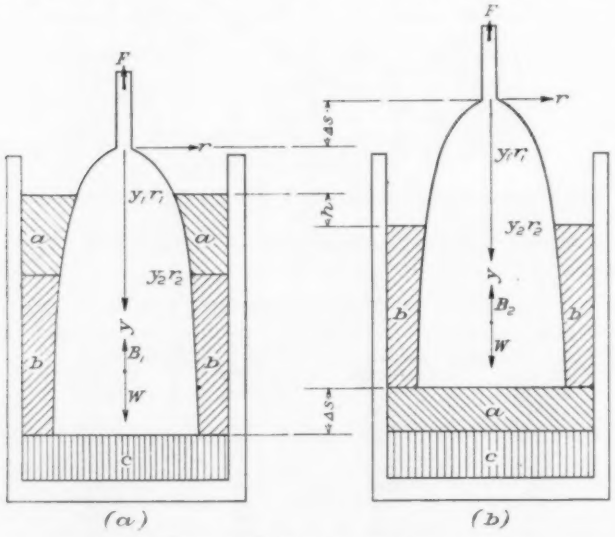

FIG. 6 DISPLACER PART OF THE MECHANISM

of total air with respect to rating, from a slightly rising one to a steeply falling one, simply by changing the balance and keeping the displacer and the mercury level in the displacer pot the same. This dependence of the characteristic on the weighting and its independence of the displacer are explained analytically in part II. The existence of this dependence had not previously been appreciated.

It is clear from this example, since the per cent total air at 200 per cent of rating is assumed, that the deadweight check determines only the shape of the characteristic curve of the meter; that is, it determines, for any radius setting, the relative values of per cent total air at different ratings. However, if the per cent total air at any one rating has been established by Orsat analysis and is used in making the deadweight calculations, the characteristic is exactly determined over the entire rating range. It is of course obvious that an assumed per cent total air value may be used, a satisfactory characteristic obtained by the deadweight method, and the Orsat analysis made last. If the Orsat analysis checks the assumed value within reasonable limits (1 to 2 per cent total air), the characteristic may be regarded to be satisfactory as originally determined. In any event, an Orsat analysis at one rating only is all that is required.

This procedure is unquestionably simpler, shorter, and more accurate than obtaining the number of Orsat checks necessary to cover the range, with the attendant probabilities of error.

PART II DETERMINATION OF THE PROPER DISPLACER CONTOUR

After making a number of deadweight checks and calculating the corresponding total air curves, it became evident that the curve of differential against boiler rating was always of the form expressed by the equation

$$y = a'x^2 + c_1$$

where y = differential
x = rating
a' and c_1 = determinable constants

In this equation the first term, $a'x^2$, represents, obviously, the differential caused by the flow of a quantity of air which is directly proportional to the rating; while the second, c_1, in reality the "weighting at zero," represents the constant differential caused by an additional quantity of air flow. Thus if the constant c_1 is zero, the flow of air is proportional to the rating, or the excess air will be constant. If c_1 is not zero, its effect will be more pronounced at the lower ratings (since the other term $a'x^2$ has a small value at low ratings) and progressively less pronounced as the rating increases. Thus when c_1 is positive, the air flow will increase from an initial constant value to values approximately proportional to the rating, giving a dropping total air characteristic; while if c_1 is negative, the characteristic will be a rising one. This is shown graphically in Fig. 5. Fig. 5(a) represents three curves of differential that might be obtained by deadweight checks. In curve B the value of c_1 is zero, in A it is a positive quantity, and in C it is a negative quantity. Fig. 5(b) represents the rates of air flow that would occur at various ratings with the corresponding deadweights, and Fig. 5(c) shows the corresponding total air characteristics. It is evident that the effect of the value of c_1 on the shape of the characteristic is of paramount importance.

Since the curve of differential is constant in form, it follows that there is only one combination of proper displacer shape and weighting to give the desired effect. To determine the displacer contour is then a problem in mechanics and the calculus.

If the arm P in Fig. 2 is considered as a free body, and any force from the pen arm through K is neglected, the equation of the force exerted by the displacer and yoke C and D must be of the same form as the equation of the differential, since that force must always exactly balance the turning force exerted by the air bells. The values of the constants a and C_2 in the new equation of force [1] may be determined from a' and c_1 for the equation of differential, using the lengths of the several arms P and L, the cross-sectional area of the draft bells, and the conversion factor for inches of water draft to pounds per square inch.

Let us now consider the displacer apart from the rest of the mechanism. In Fig. 6, F is the force acting on the meter beam. This force, as has been shown, may be expressed in the form

$$F = ax_2 + C_2 \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

Now since the displacer is a weight immersed in a fluid, the force F is

$$F = W - B \quad [2]$$

where W = the weight of the displacer, a constant
B = the buoyant force exerted by the fluid

Equating these expressions for F

$$ax^2 + C_2 = W - B$$

$$B = W - C_2 - ax^2 = K_1 - ax^2 \quad [3]$$

where $K_1 = W - C_2$

Suppose, now, that the displacer is moved upward a distance ΔS. The mercury level which before stood at the point y_1r_1 on the displacer now stands at y_2r_2, having dropped the distance h in the pot. The new buoyancy is B_2. Suppose that the distance ΔS is so small that r_2 is not appreciably different from r_1.

Then $$B_2 = B_1 - \delta\pi r^2 (y_2 - y_1) \quad [4]$$

where δ = density of the fluid displaced

Now let $y_2 - y_1 = \Delta y$

and $B_2 - B_1 = \Delta B$

Then $\Delta B = B_1 - \delta\pi r^2 \Delta y - B_1 = -\delta\pi r^2 \Delta y$ [5]

Then the average rate of change of B with respect to S is

$$\frac{\Delta B}{\Delta S} = -\delta\pi r^2 \frac{\Delta y}{\Delta S}$$

or passing to the limit as $\Delta S \longrightarrow O$, when $r_1 = r_2 = r$

$$\underset{\Delta S \longrightarrow 0}{\text{Lim.}} \frac{\Delta B}{\Delta S} = \frac{dB}{dS} = -\delta\pi r^2 \frac{dy}{dS}$$

or

$$\frac{dB}{dS} = -K_3 r^2 \frac{dy}{dS} \quad [6]$$

where $K_3 = \delta\pi$

Now in order to eliminate a variable it is advisable to valuate the quantity dy/dS. Referring to Fig. 6(a) it will be seen that the volume of fluid can be divided into three sections, a, b, and c. In Fig. 6(b) it is seen that b and c are unchanged in volume or conformation, though b has been moved upward in the pot; therefore, since the total volume of the fluid is unchanged, a in Fig. 6(b) must be equal to a in Fig. 6(a).

Hence if A is the cross-sectional area of the pot,

$$A\,\Delta S = (A - \pi r^2)(y_2 - y_1) = (A - \pi r^2)\,\Delta y$$

Then $$\frac{\Delta y}{\Delta S} = \frac{A}{A - \pi r^2}$$

And passing to the limit as $\Delta S \longrightarrow O$

$$\frac{dy}{dS} = \frac{A}{A - \pi r^2} \quad [7]$$

The change ΔS that was assumed is proportional to a change of the reading of the meter in terms of rating,

or $$\Delta x = K_2 \Delta S$$

and $$\frac{\Delta x}{\Delta S} = K_2$$

Then passing to the limit as $\Delta S \longrightarrow O$.

$$\frac{dx}{dS} = K_2 \quad [8]$$

Now differentiating Equation [3] with respect to S

$$\frac{dB}{dS} = -2ax\frac{dx}{dS} = -2aK_2 x = -K_4 x \quad [9]$$

where $K_4 = 2aK_2$

From this point, since there are two expressions for dB/dS which may be equated and an expression for dy/dS, it is simply a mathematical problem to determine r in terms of y, and S in terms of r or y. (See Appendix.)

The final equations are of the form:
for r in terms of y

$$r = \sqrt{M - \sqrt{\frac{N}{y - C}}} \quad [10]$$

for S in terms of r

$$S = \frac{PK_3^2 r^2}{a(A - \pi r^2)} \quad [11]$$

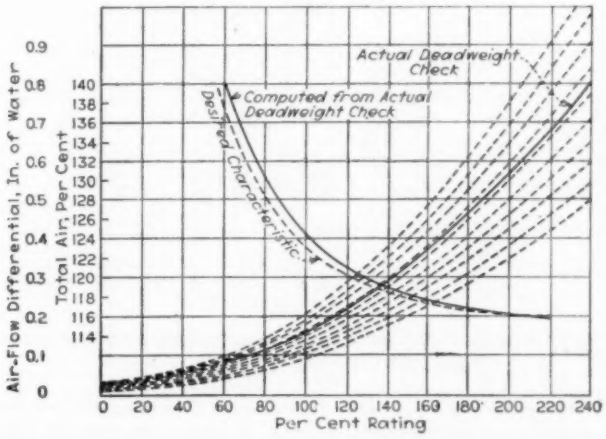

FIG. 7 IDEAL DIFFERENTIAL CURVES FOR SAME DESIRED AIR-FLOW CHARACTERISTIC

These equations are general for the air-flow mechanism in question, and the constants may be determined for any particular application.

The constants in these equations were determined for both the 400-lb.-pressure and 285-lb.-pressure boiler meters, and the graphs of the function of r with respect to y were plotted. These were compared with actual-size photographs of the displacers then in use. It was found that the displacers for the 285-lb.-pressure boiler meters checked the computed curve precisely. These displacers had been developed by cut-and-try methods by this organization some time previously. The displacers for the 400-lb.-pressure boiler meters did not check the desired contour, and it was necessary to make a templet of the computed contour and have new displacers made to that templet in the station machine shop.

From the equation of S in terms of r it was possible to determine the effect of a change of radius of the meter on the differential-rating function. From this computation it was possible to draw up a set of curves showing the differentials to be expected at various radius settings and to determine the intercept on the axis of differential—in other words, the weighting at zero—that is required for the given total air characteristic.

The family of computed differential curves for the 285-lb.-pressure boilers is given in Fig. 7. These curves show the change in differential to be expected when the radius is increased progressively in increments of 0.10 in. Any one of the computed curves of differential will produce the desired air-flow characteristic. If an actual deadweight is exactly similar to the computed curves—that is, coincident with one or dividing the interval between two in the same proportion over the entire range—it will give the desired total air characteristic.

From these computed deadweights it was then possible to determine the increment of total air that would correspond to a given change in radius when the condition of cleanliness of the boiler remains unchanged. This figure depends only on the range of radii and the normal total air. Its deviation from a constant over a range of rating is less than can be reliably measured by Orsat analysis. For use at the Hudson Avenue Station this constant has a value of 5 per cent increase in excess air per 0.1 in. increase in radius. The derivation of this factor has

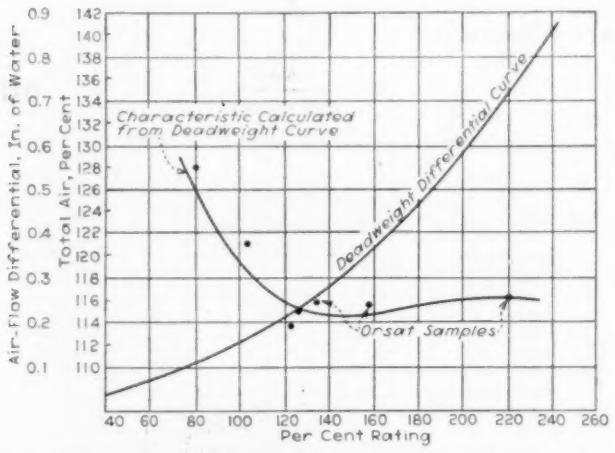

FIG. 8 COMPARISON OF TOTAL AIR CHARACTERISTIC BY DEADWEIGHT CHECK WITH FLUE-GAS ANALYSIS BY ORSAT

made unnecessary the use of the manufacturing company's comparatively complicated method involving the use of the "capacity factor."

PART III TOTAL AIR CHARACTERISTICS AND GAS-SAMPLING METHODS

It had been shown that with the correctly shaped displacer installed it was possible to control the total air characteristic entirely by manipulating the weighting at zero rating. It then became necessary to determine the characteristic desired.

This characteristic is a curve showing the excess or total air in per cent as a function of rating when the stoker is being operated with the air and steam pens together. This function determines, once the boiler and stoker are in service, the performance of the boiler; since the total air determines the stack loss directly, the refuse loss indirectly, and also the magnitude of the maintenance charges on the stoker and on furnace brickwork. Thus it is clear that assigning values of total air at which the stoker is to be operated is largely a matter of engineering judgment, rather than a problem that may be solved by precise mathematical reasoning. The principal factors to be considered are:

1 The excess air should be kept as low as possible without creating a loss due to incomplete combustion, represented by carbon monoxide in the flue gases or excessive combustible in the refuse.

2 The furnace temperature should be controlled by regulation of excess air so that the walls will not be unduly eroded by the high temperature gases or slag.

It has been found that it is possible to operate the 285-lb.-pressure boilers at as low as 110 per cent total air without any trace of CO in the flue gases at high ratings, but the furnace temperatures then run so high that the walls slag very badly. If the total air is increased to 116 per cent at 200 per cent of rating, excessive slagging of the walls stops. As the rating is decreased, the per cent total air may be kept approximately constant over an appreciable rating range, but by the time the rating has decreased to 120 per cent, the air necessary for combustion without a trace of CO has increased to 120 per cent, and at 100 per cent of rating about 123 per cent total air is necessary. Thus the characteristic that is desired for the 285-lb.-pressure boilers is that shown in Fig. 4. The meters of the 400-lb.-pressure boilers have been adjusted for approximately constant excess air throughout the operating rating range.

It then became necessary to prove that the work that had been done was justified, by demonstrating that it would pass the test "Does it work?" Everything had been based on the assumption that the differential was a true indication of the rate of air flow. The only possible check was by flue-gas analysis. The results of a series of analyses, run on a boiler that has been properly set by the deadweight check, must agree over the entire range with the characteristic predicted by the deadweight.

A series of Orsat checks was run on each boiler in the 285-lb.-pressure station to determine if these check points did coincide with the predicted curves. A typical one made before the desired total air curve had been fully agreed on is shown as Fig. 8.

Not all of the checks worked out as accurately as did this one. However, it was soon noticed that all the checks which showed inconsistent results were on boilers that were distant from the stack and that the single gas-sampling lines that were installed were on the side of the boiler away from the stack. The apparent variation of the Orsat analyses from the computed characteristics usually became greater on these boilers as the rating increased. These facts indicated the possibility that the error in the characteristic was only an apparent one, due to imperfection of the flue-gas-sampling technique rather than any true departure of these meters or boilers from the hypotheses already predicated. It was thought that, perhaps, the major gas flow was concentrated on the side of the boiler nearer the stack, due to draft conditions resulting from the offset location of the stack. If that were the case, samples drawn from either side alone would not be indicative of the average quality of the gases flowing through the boiler. It consequently became desirable to determine whether the single gas-sampling lines as then installed actually did draw representative samples of the flue gases. To do this, new sampling lines were installed in a boiler in which the difficulty was particularly serious. Two lines were installed from the north side, one running in for 8 ft. and one running in for 16 ft. This was opposite to the old single line which extended 8 ft. in from the south side. The furnace is approximately 24 ft. wide, and all three sampling lines are in the top of the third pass. The old 8-ft. line and the new 16-ft. line draw samples from about the same location. When Orsat checks were run, using all three lines, it was found that the long new line agreed fairly well with the old line, and the short new line gave widely different readings, which, when averaged with the readings from the opposite side of the boiler, checked the expected total air characteristic. The results of one of these tests are shown in Fig. 9.

When this condition was established, the necessity of a general installation of double sampling lines in all boilers was recognized. It should be kept in mind that not only must the third-pass lines provide a representative sample of the gases in that pass, but

this sample must be representative of the quality of gases flowing through the entire setting. Consequently, additional lines in the first pass to enable a check on the tightness of the setting have been found particularly helpful. With the new lines installed on all boilers, it has been possible to check the expected values of total air at all ratings and to set the meters with confidence. A series of checks, using double sampling lines in the third pass, made on one of the 285-lb.-pressure boilers after the desired characteristic had been established and checked by deadweighting, is shown in Fig. 10.

Additional data using two sampling lines, from one of the 400-lb.-pressure boilers, obtained for the primary purpose of determining the superheat curve, are included as Fig. 11. The total air characteristic was determined by a deadweight check made after the test runs had been completed and was plotted on the same graph as the results of the test.

The agreement between the total air characteristics as determined by the deadweights and checked by Orsat analysis, as illustrated in Figs. 8, 10, and 11, is perfect within the attainable

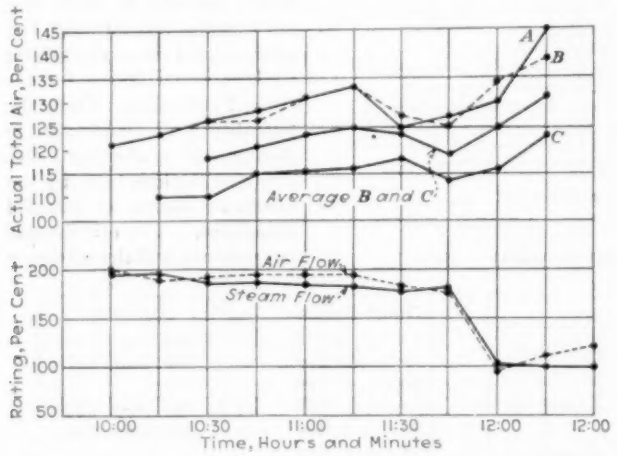

FIG. 9 COMPARISON OF SINGLE AND DOUBLE SAMPLING LINES
(Curve *A*, old line, 8 ft. in south side; *B*, new line, 16 ft. in north side, approximately same as *A*; *C*, new line, 8 ft. in north side.)

precision of measurement. The assumptions made in using the deadweight method and in deriving the displacer contour are thus proved valid.

PART IV ROUTINE FOR CHECKING METERS

As the boilers remain in service, accumulation of soot and slag on the tubes increases the draft differential between the meter connections for a given rate of gas flow. Consequently, for the same differential, the rate of gas flow will be decreased. The per cent total air with air and steam pens coincident will therefore be decreased. To counteract this action it is necessary to lengthen the radius of the meter, shown at *R*, Fig. 2.

Having established a method of meter calibration which permitted rapid and accurate manipulation of the characteristic, it became essential that a routine be developed that would insure the meters to be in proper adjustment at all times. Not only must the desired total air characteristic be determined in form, but its position must be permanently fixed (within predetermined limits) by means of successive changes of the radius length.

Moreover, a complete record of Orsat checks and radius changes with accompanying deadweight checks must at all times be kept available for easy reference.

The routine which has been developed will now be described. At intervals of ten days to two weeks, a flue-gas analysis by Orsat is run on each boiler in service. These checks are run by two men, one man analyzing samples from the 8-ft. third-pass sampling line while at the same time the other man analyzes samples from the 16-ft. third-pass sampling line and records the boiler-meter and draft-gage readings. The checks are made when the boiler is being operated so that the air and steam pens are approximately together. Five sets of samples are taken while conditions are constant, at any rating. A sample data sheet for this check is included as Fig. 12. From the Orsat analysis, the per cent total air is computed and corrected for any slight difference in the readings of the air and steam pens, to the condi-

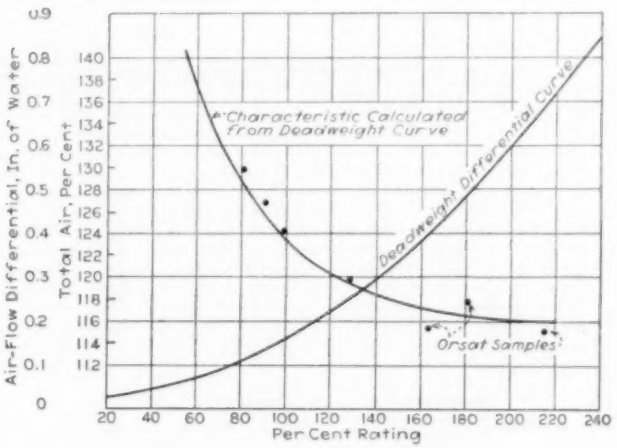

FIG. 10 COMPARISON OF TOTAL AIR CHARACTERISTIC BY DEADWEIGHT CHECK WITH FLUE-GAS ANALYSIS BY ORSAT

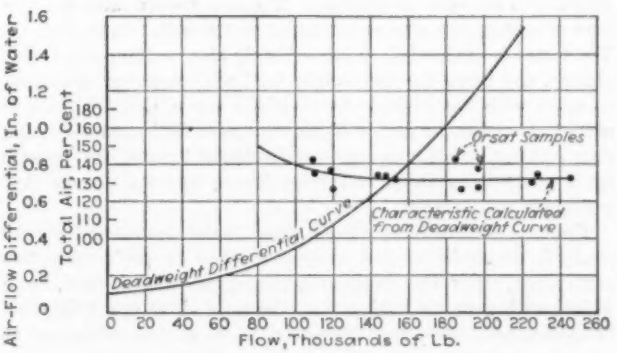

FIG. 11 COMPARISON OF TOTAL AIR CHARACTERISTIC BY DEADWEIGHT CHECK WITH FLUE-GAS ANALYSIS BY ORSAT

tion of pens exactly together. This is done by application of the formula

$$A_{pt} = A_a \times \frac{S_a}{P_a}$$

where A_{pt} = total air in per cent with pens together
A_a = actual total air, per cent
S_a = actual steam-pen reading
P_a = actual air-pen reading.

This gives the per cent total air for which the meter is set when the pens are together at the rating indicated by the air pen. The average of these data is then plotted on a sheet having on it the curve of desired total air versus rating. One of these sheets, similar to Fig. 13, which shows the record of boiler No. 14 for a three-month period, is kept for each boiler. It shows each Orsat check that is made on that boiler, its date, and the

radius at which the meter was set when the check was run. How closely the check approaches the desired condition is clearly indicated.

If an Orsat check shows that a meter is correct to within about 2 per cent total air, its setting is not changed. If the departure from the standard is greater than that limit, the radius is changed by a quantity computed from the factor of 5 per cent excess air per 0.1-in. change in radius. Radii are set only in multiples

of 0.05 in., which permits adjustment of the characteristic to within $1^1/_4$ per cent of total air. The new radius value and the date of making the change are noted on the boiler sheet, Fig. 13. The meter is deadweighted immediately after making the radius change, and when the deadweight has been computed and found to agree with the desired characteristic curve, a check mark is placed alongside the notice of the change of radius on the boiler sheet. After a radius change and deadweight check the meter is again checked by Orsat to further insure that the change that was made was correct.

The necessity of computing a great many deadweight checks made it desirable to find a short method of performing this calculation. For this purpose a nomogram was devised, from which, with a simple collineation, the total air at any rating can be determined, when the differential drafts at that rating and at a base rating are known. The nomogram for the 285-lb.-pressure boiler meters is shown with the solution of the deadweight check in Part I, as Fig. 14. On this nomogram, 200 per cent of rating was chosen arbitrarily as a convenient base, but any other value could have been used. The nomogram greatly facilitates the use of the deadweight check as a routine method.

This routine makes it possible to take care of the worst condition of any boiler in four or five hours, which allows one hour each for the Orsat checks and an hour or two, which is more than ample, for the radius change, deadweight, and its calculation. This is a distinct advance, since with the old methods of checking two or three days might be spent on one boiler, and even then there was no assurance that the meter was correctly set over the entire range.

With these methods of checking in use, only about one Orsat check in 35 gives inconsistent results, and these inconsistencies invariably disappear on additional checking. This proportion is well within the probability of error of men and instruments.

In addition, the use of this system has had some valuable by-products. It has shown that the radius of the meter need not be changed so often, nor by such large increments, as was formerly thought to be necessary. The maximum increase, over the normal period of three months between boiler cleanings, of the radius of any 285-lb.-pressure boiler meter is about 0.20 in. This corresponds to an increase in draft differential of about 20 per cent, or from about 0.60 in. of water to 0.72 in. of water at 200 per cent of rating. This is a reasonable increase, since the meter draft taps are at the top of the first and third passes, between which points there can be only a relatively light accumulation of soot as the boiler gets dirty. Most of the increase in boiler-draft loss must occur in the first pass of the boiler, and this does not affect the meter.

Knowing the normal draft drop at 200 per cent of rating for a clean boiler, it has been found possible to reset the meter radius and establish the desired total air characteristic while a boiler is out for external cleaning. Only the formality of an Orsat check is then necessary, after the boiler comes on the line, to verify the estimated degree of external cleanliness. The exit-flue-gas temperature and the efficiency

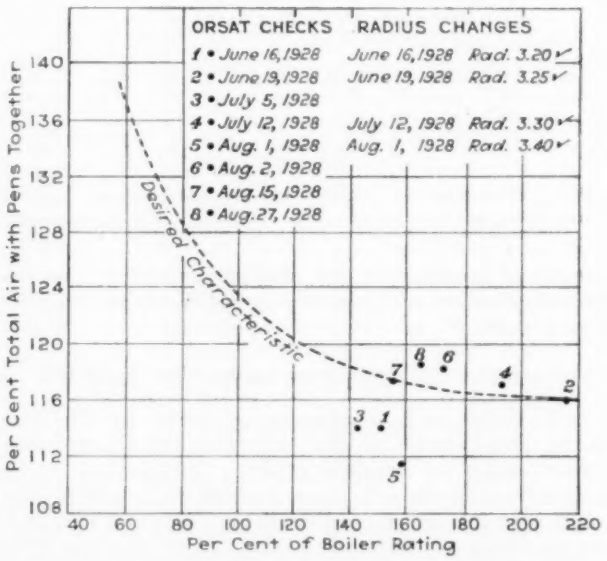

FIG. 13 RECORD OF ORSAT CHECKS AND RADIUS CHANGES

of the boiler are used as independent measures of the cleanliness of the boiler.

Furthermore, the indicated radius changes furnish a very good check on the condition of the baffling. It is apparent that if the radius change indicated by an Orsat check is not so great as it should be when considering the time that the boiler has been in service, it may very probably be that the baffling in that boiler is in bad condition.

CONCLUSIONS

The conclusions to be drawn from the data presented are

various. They cover (1) the accuracy of the use of the drop in pressure through a boiler as an indicator of rate of flow of gases and the practicability and accuracy of a meter designed to measure this flow, (2) the amount of work necessary to maintain such a meter at its maximum accuracy, and (3) the value of such a meter in conjunction with a steam-flow meter as a guide to combustion. These subjects will now be considered:

1 The difference in draft between the first and third passes of the boiler is an accurate measure of the gas flow, and a mechanism actuated by this differential draft can be constructed to indicate accurately the corresponding rate of air flow. This is evident, well this end has been accomplished can best be appreciated by the changed attitude of the operating personnel toward the efficiency of the meters as accurate combustion guides.

Results

The most important results of this work on the air-flow mechanism have been:

1 The maintenance of the stack losses at a desirably low level. This has occurred because the meters are now accepted as giving a true indication of the per cent total air. Before this work was done, a usual excuse for operating with the meter pens apart

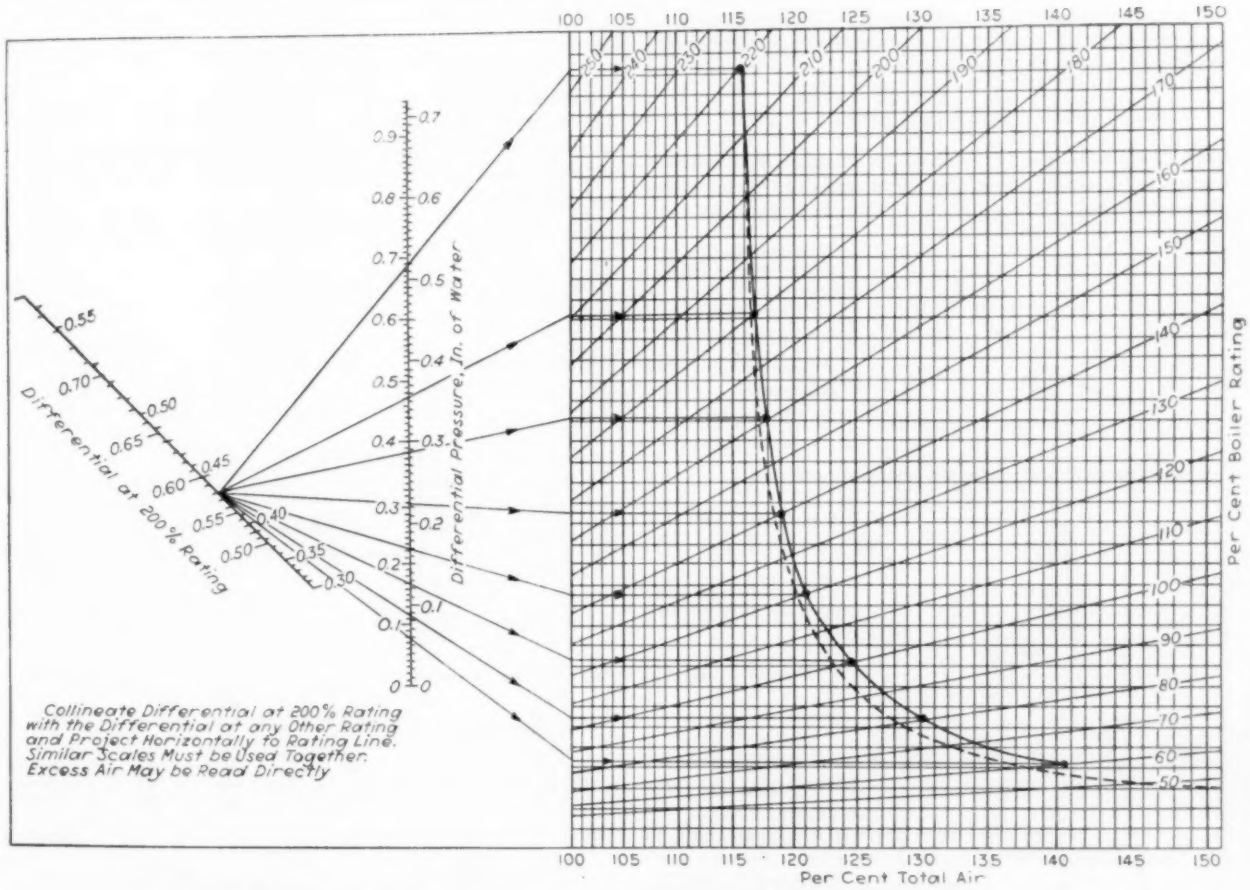

Fig. 14 Nomogram for Total Air Characteristic, 285-Lb. Boiler Meter

(Collineate differential at 200 per cent rating with the differential at any other rating and project horizontally to rating line. Similar scales must be used together. Excess air may be read directly.)

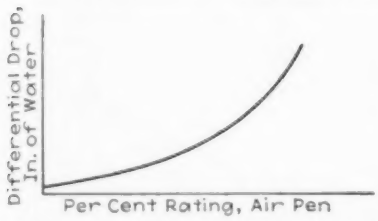
since the rate of flow predicted by the deadweight check is in such exact agreement with the flow as determined by Orsat analysis. Although, in this paper, only B. & W. three-pass cross-drum stoker-fired boilers have been considered, the principles will apply to other installations, and the displacer contour may be deduced rationally from the conditions under which the meter is to operate.

2 The maintenance of the air-flow mechanism has, by the application of the method outlined in this paper, been reduced to a completely checked routine that requires only the attention of two men for from three to five hours a month per meter.

3 The air-flow meter, maintained as described, is, in conjunction with a properly kept orifice steam meter, an absolutely reliable guide to combustion conditions. The attainment of this end was the motive for undertaking the work described. How was that the meter was not set correctly. While the meters were not always incorrect, they were so in a sufficient number of cases to cause them to be regarded as unreliable. Now, however, one can safely say that the boiler-meter indication is correct within the limits of 1 to 2 per cent of total air. The boiler-room engineers, finding that they can rely absolutely on the indication of the boiler meter, make it their business to see that the stoker attendants keep the pens together on the chart. If the pens are not kept together consistently, there is no longer any excuse; it means simply that the fires are not in proper condition. Naturally the boilers are now operated at total air values closely approximating desired conditions at all times.

2 From the point of view of calibration and adjustment of the meters, an equally great advance has been made. The maintenance of the meters in proper calibration has been rendered less

laborious as well as more effective. In a large power plant this is no small item.



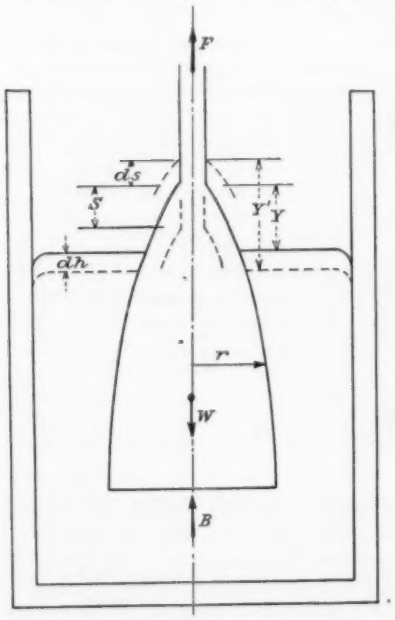
3 The ability to use the record of radii changes as a check on the condition of the exterior of the boiler tubes and baffling also represents an advance.

4 Moreover, the proper installation of meters in any extension to the boiler house is prepared for. Knowing the probable draft loss through the boiler at any rating, it is possible to determine in advance the characteristics of the air-flow mechanism for that application.

No attempt has been made to determine the monetary equivalents of the items outlined in the foregoing. It is felt, however, that it will be conceded that their beneficial influence on plant performance and cost of operation represents ample justification for the efforts involved in their attainment.

Appendix

From a series of points obtained by running a deadweight check on No. 34 boiler meter, the differential drop versus rating curve was obtained. The equation of this curve was found to be



$$D = dx^2 + C_1 \ldots [1']$$

where

D = differential drop (top of first to top of last pass)
x = air-pen rating
C_1 = y-axis intercept

F is the force which actuates the air-flow mechanism.

$$F \propto D, \text{ or } F = ax^2 + C_2 \ldots [1]$$

Now from the displacer we have at any point

$$F = W - B \ldots [2]$$

where

F = actuating force
W = weight of displacer
B = buoyancy of fluid

Equating [1] and [2], we have

$$W - B = ax^2 + C_2$$

$$B = W - ax^2 - C_2$$

$$B = k_1 - ax^2 \ldots [3]$$

where $k_1 = W - C_2$

Let us now assume S = the distance vertically above zero position of the displacer at any linear displacement. The buoyancy is B as previously assumed. The vertical length of the displacer above the mercury level at the displacement S is Y. Let us also assume the displacer is moved upward a small distance ds. The mercury level will drop a distance dh. Then $Y' - Y = ds + dh$.

Also, let us assume the distance dy is so small that the radius r does not change appreciably. Then, at the new displacement, the buoyancy will be B', where $B' = B - \delta\pi r^2 dy$.

or

$$B' - B = -\delta\pi r^2 dy \ldots [4]$$

where δ = density of fluid (mercury)
$r = f(y)$

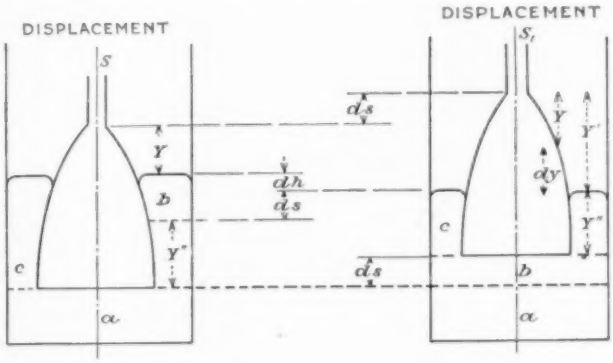
Also let $B' - B = dB$

then $$dB = -\delta\pi r^2 dy \ldots [5]$$

or $$dB = -k_2 r^2 dy$$

where $k_2 = \delta\pi$.

Dividing by dS,



$$\frac{dB}{dS} = -k_2 r^2 \frac{dy}{dS} \ldots [6]$$

Let us assume A = area of mercury pot. From the diagram the mercury may be divided into three sections, a, b, and c; $a = a$, $b = b$, $c = c$ in both cases, since the total volume is unchanged, presupposing the mercury pot is a perfect cylinder.

Then since $b = b$

$$A\,dS = (A - \pi r^2)\,dy$$

$$\frac{dy}{dS} = \frac{A}{A - \pi r^2} \ldots [7]$$

We then have

(1) $B = k_1 - ax^2$ (2) $\frac{dB}{dS} = -k_2 r^2 \frac{dy}{dS}$ (3) $\frac{dy}{dS} = \frac{A}{A - \pi r^2}$

and

$$\frac{dB}{dS} = -k_2 r^2 \frac{A}{A - \pi r^2} = -\frac{k_2 A r^2}{A - \pi r^2}$$

also

$$\frac{dB}{dS} = -2ax \frac{dx}{dS}$$

then

$$-\frac{k_2 A r^2}{A - \pi r^2} = -2ax \frac{dx}{dS}$$

and

$$\frac{k_2 A r^2}{A - \pi r^2} = 2ax \frac{dx}{dS}$$

Also $S = k_3 \times x$ (vertical displacer motion varies as pen reading)

$$dS = k_3 dx$$

$$\frac{dx}{dS} = \frac{1}{k_3} = k_4$$

Then

$$\frac{k_2Ar^2}{A-\pi r^2} = 2a\,\frac{S}{k_3}\,k_4 \quad \text{or, } S = \frac{k_2Ar^2}{A-\pi r^2} \times \frac{k_3}{k_4} \times \frac{1}{2a}$$

$$= \frac{k_3^2k_2Ar^2}{2a(A-\pi r^2)} = \frac{k_3^2k_2Ar^2}{2aA-\pi r^2 2a}$$

Let

$$k_3^2k_2A = k_5 = k_3^2\delta\pi A$$

$$2aA = k_6$$

$$2a\pi = k_7$$

Then

$$S = \frac{k_5r^2}{k_6 - k_7r^2}$$

and

$$dS = \frac{(k_6 - k_7r^2) \times 2k_5rdr - k_5r^2(-2k_7rdr)}{(k_6k_7r^2)^2}$$

$$\frac{dS}{dr} = \frac{(k_6 - k_7r^2) \times 2k_5r + 2k_5r \times k_7r^2}{(k_6 - k_7r^2)^2}$$

$$= \frac{2k_6k_5r - 2k_5k_7r^3 + 2k_5k_7r^3}{(k_6 - k_7r^2)^2} = \frac{2k_6k_5r}{(k_6 - k_7r^2)^2}$$

and

$$\frac{dy}{dr} = \frac{2k_6k_5r}{(k_6 - k_7r^2)^2} \times \frac{A}{A-\pi r^2}$$

$$\frac{dy}{dr} = \frac{2Ak_5k_6r}{Ak_6^2 - 2Ak_6k_7r^2 + Ak_7^2r^4 - \pi k_6^2r^2 + 2\pi k_6k_7r^4 - \pi k_7^2r^6}$$

$$= \frac{4A^3ak_3^2k_2r}{4A^3a^2 - 8A^2a^2\pi r^2 + 4Aa^2\pi^2r^4 - 4A^2a^2\pi r^2 + 6Aa^2\pi^2r^4 - 4a^2\pi^3r^6}$$

$$= \frac{A^3k_3^2k_2r}{a(A-\pi r^2)^3}$$

Let

$$k_8 = \frac{k_3^2k_2}{a} = \frac{k_3^2\delta\pi}{a}$$

Let

$$k_9 = k_8A^3$$

Then

$$\frac{dy}{dr} = k_8\,\frac{A^3r}{(A-\pi r^2)^3} = k_9\,\frac{r}{(A-\pi r^2)^3} \quad \text{and} \quad dy = \frac{k_9rdr}{(A-\pi r^2)^3}$$

Let

$$U = A - \pi r^2$$

Then

$$dU = -2\pi rdr \quad \text{and} \quad dy = \frac{k_9 2\pi rdr}{2\pi U^3}$$

Then

$$dy = \frac{k_9dU}{-2\pi U^3} = \frac{k_9dUU^{-3}}{-2\pi}$$

and

$$y = \int \frac{-k_9U^{-3}dU}{2\pi} = \frac{-k_9}{2\pi} \times \frac{U^{-2}}{-2} + C$$

$$d\,\frac{U^{-2}}{-2} = \frac{1}{-2} \times -2U^{-3}dU = U^{-3}dU$$

$$y = \frac{k_9U^{-2}}{4\pi} = \frac{k_9}{4\pi U^2} = \frac{k_8A^3}{4\pi U^2}$$

$$y = \frac{k_8^2 \times \delta\pi A^3}{4\pi aU^2} + C = \frac{k_3^2\delta A^3}{4a(A-\pi r^2)^2} + C$$

We then have:

$$(a) \quad S = \frac{k_3^2\delta\pi Ar^2}{2a(A-\pi r^2)} + C$$

$$(b) \quad y = \frac{k_3^2\delta A^3}{2 \times 2a(A-\pi r^2)^2} + C$$

Dimensional check:

$$\text{in.} = \frac{\text{in.}^3 \times \frac{\text{lb.}}{\text{in.}^3} \times C \times \text{in.}^2 \times \text{in.}^2}{\text{lb. (in.}^2 - C \times \text{in.}^2)} = \text{in.}$$

$$\text{in.} = \frac{\text{in.}^3 \times \frac{\text{lb.}}{\text{in.}^3} \times \text{in.}^6}{\text{lb.} \times (\text{in.}^2 - C \times \text{in.}^2)^2} = \text{in.}$$

Final Equations

$$F = ax^2 + C_2 \qquad [1]$$

$$F = W - B \qquad [2]$$

$$B = W - ax^2 - C_2 \qquad [3]$$

$$S = k_9x \qquad [4]$$

$$S = \frac{k_3^2\delta\pi Ar^2}{2a(A-\pi r^2)} + C \qquad [5]$$

$$y = \frac{k_3^2\delta A^3}{4a(A-\pi r^2)^2} + C \qquad [6]$$

$$r = \sqrt{\frac{A}{\pi} \pm \frac{Ak_9}{2\pi}\sqrt{\frac{\delta A}{a(y-c)}}} \qquad [6']$$

Discussion

A. E. Livingston.[2] It is evident that the paper is the result of much experience with boiler meters and of real constructive thinking. There are a few questions that the writer would like to ask regarding points in the paper. In one place it reads: "Simultaneous gas analyses and draft differentials with coincident pen readings were found to be rather confusing. While individual Orsat checks were shown to be correct or incorrect, as the case might be, an inconsistent function of draft against rating was indicated, showing a minimum draft point at about 125 per cent of rating. As the rating decreased below 125 per cent, the differential draft increased. If this were a true indication of the calibration of the meters, they would be practically valueless below 150 per cent of rating. Such was probably the case for the condition in which the meters then were. However, there was so much uncertainty concerning the accuracy of the draft readings that this method was discarded in favor of the 'deadweight check.'"

Did the calibration of the meter give such a rapid increase in total air as the rating dropped below 125 per cent that the actual volume of air passing through the boiler increased? If not, then does not this contradict the assumption made in the next paragraph, that the differential draft between the first and third passes is exactly proportional to the square of the flow?

The assumption is made that the differential draft is exactly

[2] Efficiency Engineer, Staten Island Edison Corporation.

proportional to the square of the flow, the boiler acting as a conduit. Is this based on volume or weight of gases? What will be the effect of change in specific gravity of the gases due to change in temperature and pressure? The change in temperature and pressure may be caused by either change in total air, change in rating, or both.

One of the reasons given for using the "deadweight check" method is that it is more accurate than obtaining a number of Orsat checks to cover the range. By using only one Orsat check,

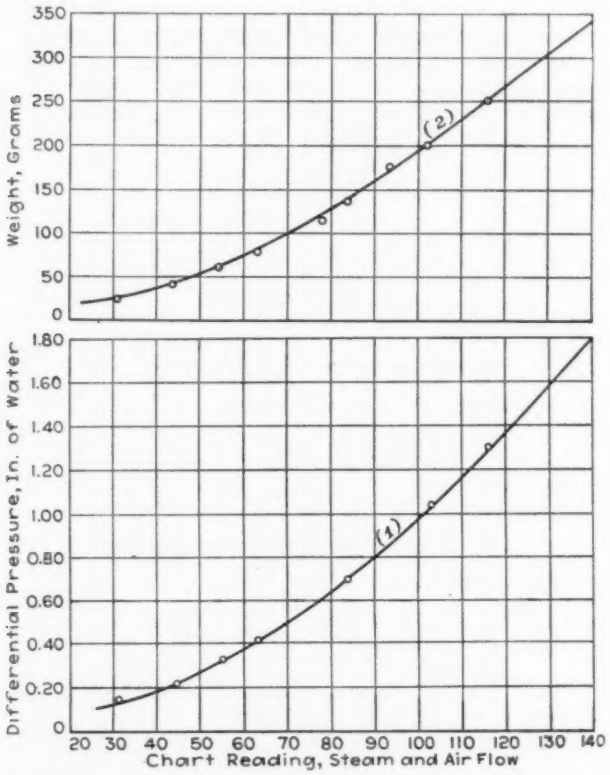


FIG. 15 AIR-FLOW SETTING, BAILEY METER, BOILER NO. 1
(Curves for 120 per cent, all ratings. Curve 1, differential pressure on air-flow bells; Curve 2, weights to be used in calibrating air-flow mechanism.)

is not the possibility of error increased? If a number of Orsat checks are made and plotted, error in any set will show up.

The author's whole procedure is built up on the assumption that the square root of the differential varies directly as the product of rating times total air. If this is true, as he has satisfied himself it is, why cannot the following short cut method be used? Run two tests at different ratings, plot square root of differential against product of rating times total air, and draw a straight line through the two points. From this line any differential could be computed for any rating and any total air. Data could readily be obtained for a differential versus rating curve, and corresponding grams-weight versus rating curve and the meter set accordingly. The grams-weight curve is used because it is easier to change weights on the bell than it is the air pressure under it when calibrating the meter.

The calibrating of the meter to give desired total air is the objective of the operating man. If he cannot succeed in doing this with the displacer supplied, would not the manufacturer's engineers be better fitted by experience to redesign the displacer? Would not the grams-weight versus chart reading curve be sufficient data for the design of the displacer by the manufacturer's engineers—assuming, of course, that they have complete details of the meter?

It is certainly an accomplishment for a test engineer, with the many demands on his time and attention, to work up the involved computations necessary for the design of an air-flow displacer. The author is to be commended very highly.

The experiences of the Staten Island Edison Corporation with boiler meters and the method of obtaining the desired calibration are outlined in the following covering the practice of the Test Department of the company.

AIR FLOW

These are a few of the questions that the test engineer responsible for boiler meters has to consider: How many trials must be made before one can get a final satisfactory adjustment on the boiler meter? Can one get a setting which gives the desired total air (either constant or variable) at all ratings? How near representative of average are the flue-gas samples used? What effect on the setting does variation in feedwater temperature have?

The Livingston Station has two bleeder-type turbines normally

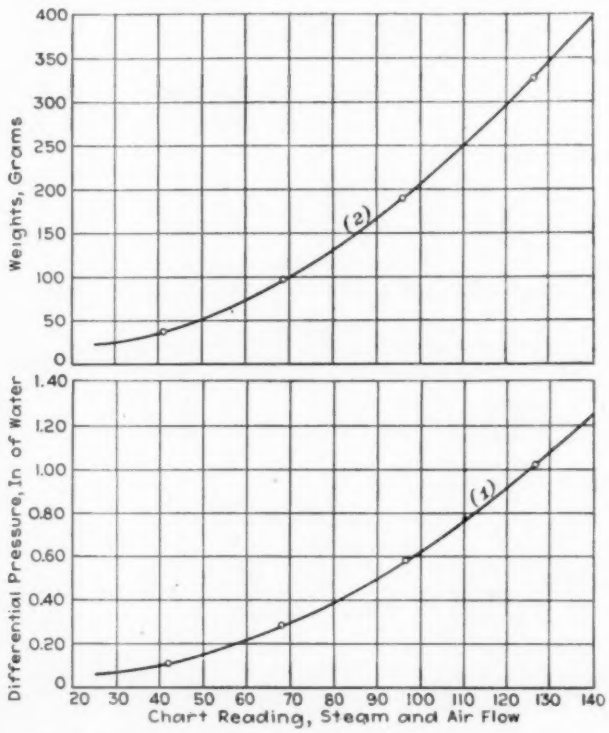

FIG. 16 AIR-FLOW SETTING, BAILEY METER, BOILER NO. 3
(Curves for varying percentage total air; straight line, 130 per cent at 100 per cent rating, 120 per cent at 350 per cent rating. Curve 1, differential pressure on air-flow bells; Curve 2, weights to be used in calibrating air-flow mechanism.)

operated with feedwater leaving heaters at approximately 230 deg. fahr. (varying with load). When one of these turbines is out, a non-bleed turbine is operated with condensate temperature about 70 deg. fahr. The variation in feed temperature and resultant variation in steam temperature cause the factor of evaporation to vary from 1.12 to 1.20, or 7 per cent. Thus the steam flow for a given heat absorption and a corresponding fixed air flow may vary 7 per cent.

Setting the meters, according to instructions of the manufacturer, for desired total air at 300 per cent rating has given much too high total air at lower ratings on two meters and much too low on one meter. Setting according to the manufacturer's instructions will be referred to as the "capacity factor" method.

Numerous Orsat readings were taken in the attempt to obtain satisfactory setting by the capacity-factor method. The results were unsatisfactory, for two reasons—one is explained in the foregoing paragraph and the other was due to taking the flue-gas sample from one point only (one-third of width of boiler setting from one side). With a perfect fire, the sample from one point only might be representative, but fires, like human beings, may be good but are never perfect.

For obtaining total air two Orsats are now used—one on each side of the boiler, with the sample line one-third of the way across the setting. Total air thus obtained varies from a close check to 20 per cent difference (120 per cent on one side, 140 per cent on other side) in the average of ten readings.

A direct method has been found to be positive in giving the desired meter calibration. Determine the desirable total air and take readings at four ratings, approximately 100, 175, 250, and 325 per cent.

Three men are required to obtain the test data. Two men operate Orsats, compute total air, and read steam temperature. One man operates the stoker and reads steam flow, steam pressure, differential pressure across bells of meters, and feedwater temperature. (Other readings are taken; only those noted are used for setting the air-flow mechanism.)

Total air values obtained from Orsat readings are given immediately to the man operating the stoker, who makes necessary adjustments to keep the total air close to the desired value.

For given heat absorption, three variables affect the steam flow as indicated by the meter—pressure, superheat, and factor of evaporation. If either or all of these items were not normal during test, corrected steam-flow values are computed. The corrected values are used in plotting meter curves.

Two curves are plotted, differential pressure and grams weight, against the corrected chart readings (see Figs. 15 and 16). Grams weight is obtained by converting inches of water to equivalent grams and multiplying by area of air-flow bell. These computations may be checked by taking readings of the air-flow pen during tests, then applying the computed weight on the air-flow bell, with lines to the boiler disconnected, before any change is made. It is desirable to take a differential reading to eliminate possible error due to friction or rubbing in the air-flow mechanism.

Air-pressure lines from the boiler are disconnected, and the air-flow radius is changed until weights on the meter bell produce chart readings in accordance with the curve. If the meter cannot be made to check the curve properly at both high and low ratings by changing the radius, then increasing or decreasing the mercury in the displacer reservoir and shifting the rider weights will usually make possible the following of the curve very closely.

It should be noted that by this method only one series of readings is taken and that the work can be completed by one man after the readings are taken. No check readings are needed as the check lies in the grams-weight versus the steam-flow curve. By this method the meter can be set for normal conditions regardless of the feed and steam temperatures prevailing at time of test.

Stoker Speed

The meter is equipped with a tachometer for recording the stoker speed. The mechanism in the meter is similar to the air-flow mechanism and may be calibrated by using the grams-weight versus chart reading curve similar to that used for the air flow.

The ideal condition would be to have the stoker-speed pen calibrated to the steam-flow pen as is the air flow. Having three pens recording together would make the record confusing. In order to have the meter serve the fireman as a guide for the stoker speed and give a record for checking purposes, without having a confusing and unreadable chart, the stoker pen is calibrated to stay a definite distance away from the steam-flow pen. At the Livingston Station the full range of the chart is seldom required for the steam flow, so the stoker pen is set five spaces above the steam flow. Five spaces are used because every fifth line is a major chart division. Zero for this pen is then one major space above chart zero.

To obtain the grams-weight versus chart reading curve, there are first taken the readings of stoker speed and differential pressure acting on the stoker-speed bells. The differential pressure is converted to equivalent force, in grams, acting on the bells. This data is plotted as shown in curve 1 on Fig. 17.

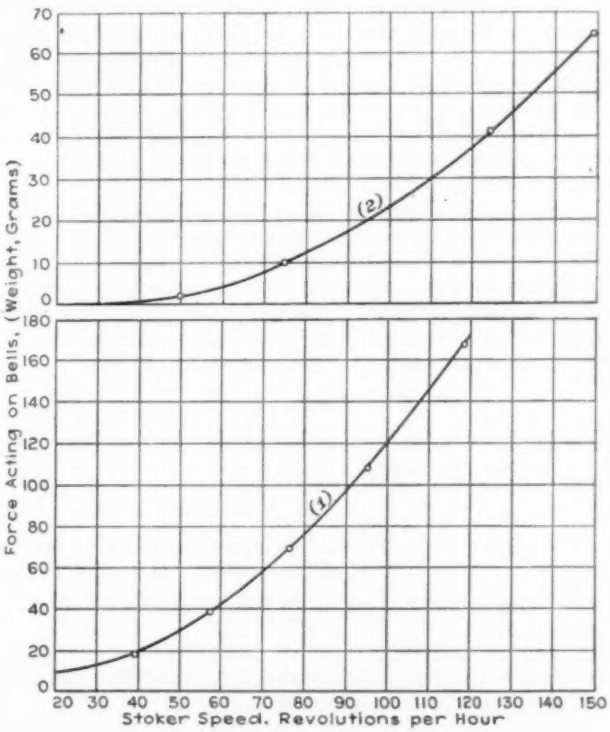

Fig. 17 Boiler Stoker Tachometer

There are known the average amount of coal fed to the boiler per revolution of the stoker and the pounds of steam produced per pound of coal. The steam flow as recorded by the meter has been found to be very inaccurate, so it was necessary to check each meter separately against a feedwater meter. A correction factor thus obtained is used in computing stoker speed required for various steam-flow pen readings.

Suppose there has just been found the stoker speed necessary to keep the steam-pen reading at 50 (one thousand pounds) on the chart. From curve 1, Fig. 17, there is found the force in grams acting on the meter bell at this speed. When the steam flow reads 50 (one thousand pounds), it is desired that the stoker pen should read 75; thus there is shown one point on curve 2. Other points are obtained in the same way.

The meter mechanism is then adjusted, using curve 2, following a procedure similar to that used for adjusting the air-flow mechanism.

A. A. Markson.[3] The writer hopes that it will please the author to know that this excellent paper has stimulated some lively thinking on the subject in the writer's organization.

[3] Mechanical Engineer, New York Steam Corporation, New York, N. Y. Jun. A.S.M.E.

Unless the writer has misunderstood the paper, he caught the fundamental point of the work as follows: The weight of gases passing through the setting may be proportioned to the square root of the draft loss across a properly selected portion of the setting by means of an intercept equation of the form:

$$Y = A'X^2 + C_1$$

The problem is, therefore, reducible to the determination of the general equation of the displacer so that the curve satisfies A' which is implicit in Equation [10].

It is obvious that C_1 is of the nature of an intercept comparable to stack effect. Unless by design, it can be made sensibly equal to zero, and it would appear, for the case given by the author, C_1 reduces to zero, for constant excess air, and need not be considered because when X is zero, C_1 is zero in his boiler (Fig. 1).

The validity of his calculations, therefore, depends on the assumption that A' is fundamentally a constant. The writer believes the fact that it worked out as a constant should be considered in the light of being a special case.

The constancy of A' depends on the assumption that the differential draft loss is proportional to the square of the gas flow. This seems only true if the heat transmission in the boiler, or rather the mean temperature of the gases under consideration, did not change with the flow, or at least was of a very small order of change. This is generally by no means so. Let us write for the weight of gas passing the draft apparatus per second

$$M_1 = FA(2g)^{1/2}D_1H_1^{1/2}$$

in which M_1 = weight of gases per second
F = a coefficient of resistance
A = an area
D_1 = mean density of gas
H_1 = the differential in homogeneous feet of gas in question and is equal to $D_1H_1/62.4$ feet of water

But $$D = D_0\frac{460}{T_1}$$

where D_0 is the standard density of the gas and T_1 is the absolute temperature, °R corresponding to D_1.

The expression for M_1 reduced to draft loss in feet of water is therefore

$$M_1 = FA(2g)^{1/2}D_0\frac{460}{T_1}\left(\frac{T_1}{460\,D_0}\times 62.4\times HW\right)^{1/2}$$

in which HW_1 is the draft loss in feet of water, or $M_1 = KT^{-1/2}HW_1^{1/2}$ constants being combined. For any other value of M, if T also changes

$$M_2 = KT_2^{-1/2}HW_2^{1/2}$$

In other words,

$$\frac{M_1}{M_2} = \frac{(T_2)^{1/2}}{(T_1)}\frac{(HW_1)^{1/2}}{(HW_2)} \quad \ldots\ldots\ldots\ldots\ldots [1]$$

rather than

$$\frac{M_1}{M_2} = \frac{(HW_1)^{1/2}}{(HW_2)} \text{ as assumed} \quad \ldots\ldots\ldots\ldots [2]$$

Using [1] instead of [2] is easy of application to any boiler. Undoubtedly it may explain the inconsistency of the curve which gave a higher draft at a lower rating. It is rational, for one thing. The effect of viscosity of gases can be neglected, in the writer's opinion, for it is not the absolute viscosity which counts, but the kinematic viscosity which does not change as much. The assumption that the actual resistance is sensibly constant over a limited range seems reasonable to the writer.

C_1, if pure stack effect, had best be made zero in the installation if possible, as it will also vary with changes of temperature. It is usually easy to do this.

The writer would like to comment on the general scheme of using the boiler meter at high ratings on stokers. The author's statement is that excess air should be kept as low as is compatible with furnace temperatures and ashpit combustible. This might be modified as applying particularly to high rates of combustion as follows: The excess air should be kept as low as furnace temperatures will allow, until a point is reached at which the gain due to decreased cinder carry-off with lowered excess air is offset by increased ashpit and CO losses. There is no doubt that the effect of cinder carry-over increases much faster at high excess air than the compensating effect of lower ashpit combustible. Of course, smoke is another factor which may have a somewhat more indefinite bearing on efficiency than the previous factors spoken of, but which nevertheless must modify combustion conditions in accordance with the plant location.

H. M. Hammond.[4] The author has given an excellent paper and is to be commended for the valuable and interesting data which he has presented. As a representative of the manufacturer of the boiler meter, the writer wants to say that we are heartily in favor of having customers make careful studies of the adjustments to be made in this meter. By going into this problem as thoroughly as he has, the author has insured that his company will realize a maximum return on their investment in boiler meters. The boiler meter, after all, is only a means to an end. When properly installed and adjusted, it will show what the operating conditions are—whether the proper amount of air is being used for best economy; and it will show the changes which should be made to improve efficiency. The results obtained are, in a measure, dependent upon the interest and attention given the meters by the operators.

The meter company renders from one to two days' service work per meter in connection with every boiler-meter installation, but it cannot possibly render sufficient time to do the thorough and complete job which the author has done, without making an additional service charge for such work. A staff of service engineers is maintained in all of the company's branch offices located in the principal cities throughout the country which is available for this service when desired.

Several years ago the most common and the largest controllable loss in boiler operation was due to the use of extremely high excess air. In attempting to reduce this loss it was only considered necessary to reduce the quantity of air used so as to maintain a lower but substantially constant excess air at all boiler ratings. With the comparatively small ranges over which the boilers were operated this was not difficult to do.

With the advent of modern stokers, pulverized-coal firing, turbulent burners, highly preheated air, water-cooled furnace walls, and other important developments, permitting the operation of boilers over much wider ranges in rating, other important limiting factors in determining the proper excess air to use for best overall results have presented themselves. Some of these factors are smoke, unburned-gas loss, refractory deterioration, the burning of stoker parts and burners, and carbon loss to the stack or into the ashpit. In at least one instance of which the writer has knowledge, the most economical excess air proved to be that which would give the desired reheat-steam temperature. In other words, in this particular case it was found that by using a higher excess air than was conducive to best combustion efficiency, in order to increase the reheat-steam temperature, the

[4] Sales Manager, Bailey Meter Company, Cleveland, Ohio. Assoc-Mem. A.S.M.E.

turbine efficiency was increased by more than enough to offset the decreased combustion efficiency.

It has been found that the above-mentioned factors or losses appear at different boiler ratings, and the magnitude of each varies with rating, so that in recent years it has become necessary, in many cases, to adjust the air-flow mechanisms in boiler meters for a variable excess air with rating.

In one case, for instance, where 3000-hp. boilers equipped with air-cooled furnace walls are fired with pulverized coal using the bin system with vertical down-shot burners, it is possible, as shown in Fig. 18, to operate with 25 per cent excess air up to 100 per cent of boiler rating. From this point the excess air is gradually increased with rating until it reaches 69 per cent at 350 per cent of rating. The limiting factor at the lower part of the curve is smoke, whereas refractory deterioriation is the criterion above 100 per cent of rating.

In another installation comprising pulverized-coal-fired boilers of approximately 2700 hp. each and using water-cooled furnaces consisting of bare water tubes set in recesses in the refractory

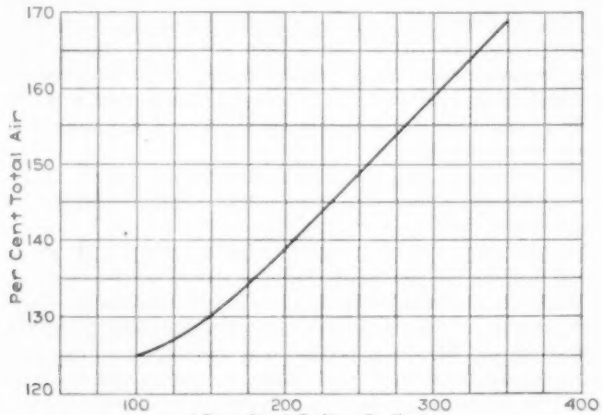

FIG. 18

wall, the boiler meters are adjusted to give 30 per cent excess air at 100 per cent of rating, 14 per cent excess air at 200 per cent of rating, and 33 per cent excess air at 350 per cent of rating, as shown in Fig. 19. In this case 30 per cent excess air is required at 100 per cent of boiler rating to prevent smoke. As the rating increases and a higher furnace temperature is obtained, the excess air may be gradually decreased to a minimum of 14 per cent at 200 per cent of rating. As the boiler rating is increased above 200 per cent the increased furnace temperature causes the refractories to start to run unless the excess air is again gradually increased with increased boiler rating.

In the last two installations mentioned, as well as in the case of a dozen or fifteen other installations in the larger central stations where a comparatively large variation in excess air with rating has been found advisable, we have designed special air-flow displacers, as was done by the author for the boiler meters at the Hudson Avenue Station.

Where only a small variation in excess air is required and where the excess-air curve is approximately a straight line, such as a gradual variation of, say, from 20 per cent excess air at 140 per cent of boiler rating to 30 per cent excess air at 240 per cent of rating, the adjustment may be made with the standard parabolic displacer by simply changing the radius R, referred to in the paper, the amount of mercury in the air-flow displacer reservoir and the positions of the balance weights.

In addition to the desirability of adjusting the boiler meter for a variable excess air with rating in order to insure best operating efficiency at all times, as outlined, it may be necessary to adjust the air-flow mechanism for something other than the standard-gram-weight calibration curve in order to accurately compensate for a number of variables in boiler operation.

There are certain factors, for instance, such as an increased flue-gas temperature with rating, an increased superheated steam temperature with rating, an increased steam pressure at the meter orifice with rating, and a decreased boiler efficiency with

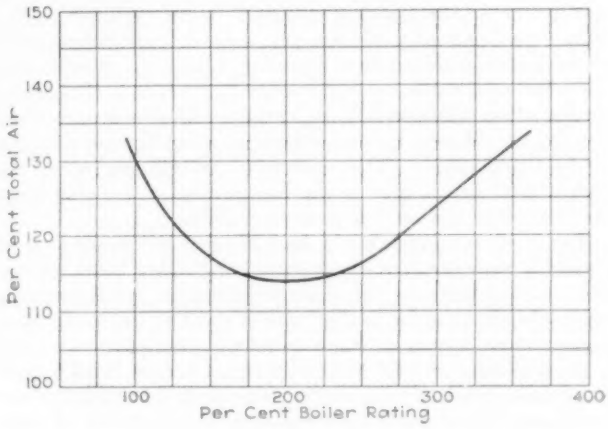

FIG. 19

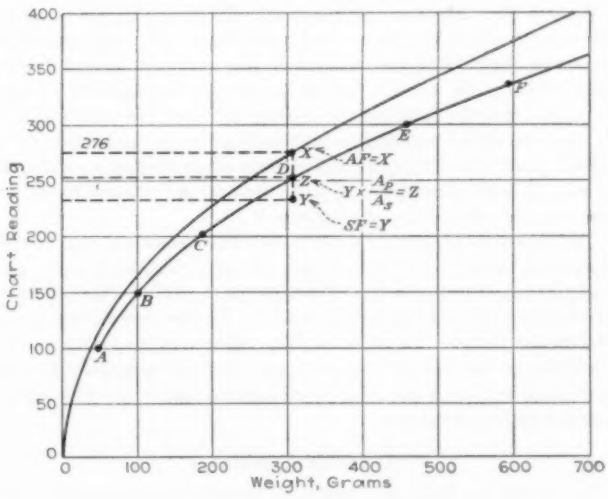

FIG. 20

rating which must be taken into consideration in adjusting the steam-flow—air-flow relationship if the excess air is to be held within very close limits at all boiler ratings. This is accomplished by making the air-flow adjustment on the basis of meter readings and complete gas analyses taken at several boiler ratings. The boiler meters in the larger power plants where it is desired to hold the excess air within 2 or 3 per cent of that corresponding to most efficient conditions should be adjusted in this manner.

The usual procedure in making an air-flow adjustment of this nature is, first, to run a dead-weight or gram-weight calibration of the air-flow recorder. A curve, such as the upper curve in Fig. 20, should then be plotted with gram weights as the abscissas and the corresponding chart readings of the air flow as the ordinates. After the dead-weight calibration has been obtained, a number of complete-combustion tests should be run on the

boiler at different rates of steaming. After having properly analyzed the results and having determined the proper excess air at each of the rates of steaming, horizontal lines are drawn on the dead-weight calibration curve at the average readings of the air-flow during the various tests. At all points where these lines cross the original dead-weight calibration curve, vertical lines such as XY in Fig. 20, are drawn, and on these lines new points such as Z, for the final air-flow calibration curve, are placed. Each of these points is determined by multiplying the average corrected steam-flow reading Y during each test by the ratio of the observed total air during the test to the desired total air for that particular rate of steaming A_p/A_s. In other words, the point on the new curve Z equals $Y \times A_p/A_s$. The curve through these points determined by the results of several combustion tests at different ratings is the new calibration curve for the air-flow mechanism. When calibrated to this new curve the desired total air will exist at the various rates of steaming when the steam-flow and air-flow pens are together.

Too much emphasis cannot be laid upon the importance of obtaining representative gas samples in adjusting boiler meters. The gas-sampling tube should be shifted about in all directions across the gas passages in the boiler in order to locate the most representative spot from which to take gas samples.

A certain amount of stratification seems to exist in all boilers. It appears practically impossible to properly mix burnable elements and the oxygen in the air in equal proportions in all parts of the furnace, and for this reason gas samples taken from different parts of the exit-gas passage will show different percentages of excess air. More excess air is usually shown in gas samples taken near the sidewalls of the boilers than from samples taken near the center, and the amount of this variation should be determined. It is equally important to take a number of gas samples from the front to the rear of the last pass of the boiler in order to detect stratification from front to back, if any. It is also important to determine the amount of air infiltration through the boiler setting before making an air-flow adjustment based on gas samples taken from the boiler exit.

A large pulverized-coal-fired boiler was recently found to be operating on 10 per cent excess air as determined from gas samples taken from the top of the first pass of the boiler, whereas the boiler meter had been adjusted for 25 per cent excess air at the boiler outlet. In other words, there was considerable infiltration of air through the setting so that gas samples taken at the boiler exit were far from being representative of combustion conditions in the furnace.

Author's Closure

It should be kept in mind that different installations have different requirements of excess air versus rating, and this paper does not pretend that the conditions desired at the Hudson Avenue Station should necessarily prevail elsewhere. However, the theories presented are general, and the fundamental principles outlined are applicable to other installations.

In connection with Mr. A. E. Livingston's difficulties regarding the use of the "capacity factor method," this method was discontinued at the Hudson Avenue Station, and the factor of 5 per cent excess air per 0.1 in. change in radius is used, for simplification only. The capacity-factor method presupposes that the meter has a particular characteristic. It may be suggested that herein lies Mr. Livingston's apparent difficulty.

In answer to Mr. Livingston's first question, it is admitted that the results were found to be rather confusing at the outset of the work. This confusion was the condition which necessitated the development of a new or different procedure and resulted in the "deadweight check" calculations. It is felt, however, that rust and sediment within the air bells on certain meters, which would result in a varying cross-sectional area of the bell at the surface of the oil as it is withdrawn, were large contributing factors in causing some of these confusing indications.

The square law is applied to the weight of gas and not to the volume. The effect of the change in specific gravity of the gases will be amplified under the reply to Mr. Hammond.

The use of an Orsat check at only one rating does not increase the possibility of error over a procedure requiring a series of Orsat checks. This is due to the fact that the tabulated records present a continuous picture of conditions and make each individual check practically a complete story when compared with the per cent total air obtained on previous checks. With increase in length of service and no change in the radius of the boiler meter, the per cent total air should decrease provided the baffling and setting have not deteriorated. As explained in the paper, it is this complete record of all Orsat checks which permits deductions concerning baffle conditions. It is true that possibly one check in every 35 will give an unreasonable Orsat analysis when compared with past indications. An additional check will invariably agree with the past record or substantiate an abnormal condition. Changes to the radius length are even forecast, and the Orsat checks then are merely formalities. This, however, would not be the case were it not for the complete record of all data pertaining to each air-flow mechanism, in which event procedure on the basis of an Orsat check at only one rating would be impossible.

Mr. Livingston suggests a short-cut method, but it is not evident wherein making two Orsat checks is simpler and shorter than making one.

In connection with the question raised by Mr. V. M. Frost, actual evaporation and boiler efficiency should not be confused. It is granted that the boiler efficiency is not a constant. However, neither is the feedwater temperature which both Mr. Livingston and Mr. Frost pointed out. As the rating increases and the boiler efficiency drops, more coal per pound of steam would be required, assuming the feedwater temperature to be constant. However, as our rating increases, our feedwater temperature increases, which of itself would require less coal per pound of steam. Thus, the feedwater temperature change obviously has a counteracting effect on the efficiency. Mr. Frost also mentioned weighed-water test conditions at which time the feedwater temperature is extremely cold in comparison with normal conditions, and the steam-flow—air-flow relation is affected in consequence. Abnormal conditions existing but occasionally on individual boilers should not be considered. Under normal operating conditions, feedwater temperature changes do not cause any difficulty. As a matter of fact, they are desirable to counteract the change in efficiency. Additional variables affecting the accuracy of the assumptions will be discussed under the reply to Mr. Hammond.

Mr. Markson questions the equation $y = a^1x^2 + c_1$, apparently overlooking the fact that the Orsat analyses check the predicted curves based on this equation. In connection with c_1 being the stack effect, this would be true provided stack effect were not compensated for by proper location of the draft taps, as is the case of the installations at the Hudson Avenue Station.

Mr. Worth expressed a fear that the boiler meter seems to present too complicated a problem for the small industrial plant. The situation is not quite as bad as it might at first appear. It must be remembered that the data presented in the paper were founded on the operation of large boilers operating at high ratings. The resulting high furnace temperatures cause comparatively rapid slagging of the boiler tubes. The action of the meter is such that, with increase in boiler service, the per cent total air will decrease without adjustments to the meter. In the industrial plant these conditions are not as severe, the ratings and tempera-

tures being relatively low. Moreover, it is not usually as essential that the absolute maximum of efficiency be obtained as is the case in the central station, since the coal consumption is not nearly so great. Consequently, if the industrial plant starts out with the type of characteristic desired, but the radius slightly longer than it should be, the natural slagging action of the boiler will gradually lower the curve in position without changing its shape. Before very long the characteristic will be in exactly the desired location. The boiler will consequently operate continuously at a fair average, and for a portion of the time the meter will be absolutely correct.

Mr. Hammond mentioned increase in flue-gas temperature, increasing steam temperature and decreasing boiler efficiency as variables affecting the steam-flow—air-flow relation. It may be well at this time to add a few more for completeness; namely, change in stack effect, change in feedwater temperature, the fact that although the meter is to measure air flow the actuating medium is flue gas and that increase in flue-gas temperature affects not only the volume but also the density and viscosity. The last two influence the friction factor coefficient. Moreover, the change in steam temperature affects not only the f.o.e., but also the steam-pen reading. It is next to impossible to evaluate and sum up these variable influences. Moreover, some are admittedly positive and some negative, and consequently tend to compensate one another. An attempt was made to evaluate these variables, resulting in a net computed error of from about +3 per cent to —4 per cent, depending on the variation in the friction coefficient. Under certain conditions the net error was calculated to be zero. However, the Orsat is the cornerstone on which the entire structure must either stand or crumble, and when the Orsat was used to check the curves predicted by the "deadweight check," verification of the correctness of our procedure was definitely established. This is the conclusive proof that the variables actually do compensate and that their net effect must be zero within the limitations of the measurements.

In closing, it may be of interest to state that the methods outlined in this paper are being successfully applied to the meters in the Gold Street Station of the company, where the boilers, stokers, and meters are different from the Hudson Avenue Station installations.

In addition, any one desirous of inspecting the complete record of the meters and observing the operation of the boilers at Hudson Avenue is cordially invited to visit the station.

Power and Heat in the Industrial Plant

General Aspect of the Problems Involved—Power and Steam-Heat Relations—Size Effects—Investment and Operating Costs—Examples of Industrial Installations

By R. J. S. PIGOTT,[1] NEW YORK, N. Y.

THE study of this subject has in the past two or three years received an amount of attention much more commensurate with its importance than it did prior to that time. One reason is that the increase in size of industrial plants has increased the amount of money involved; another is that it is now realized that a dollar saved in producing power or heat is just as valuable as one saved by improving the process employed in its generation.

For most industrial plants the cost of power, and often of heat, has been a very small percentage of the total production cost, and consequently consideration of power cost has been subordinated to the larger savings obtainable in the production process. For example, the total cost of power, building heating, process heat, water, etc., in the manufacture of military rifles was $0.28 out of a total cost of $18—a matter of 1.5 per cent; but the total bill for these services was $60,000 per month.

Another very powerful factor opposing improvement in power and heat production is quite natural and human: the operators of the plant, experienced by years in their own production, feel that few can tell them much about it—and this idea is automatically transferred to all the factors connected with production, which includes power and heat. The result is that the operators of an industrial plant have in general resisted, often strenuously, any attempts on the part of power and heat specialists to offer advice or help for the solution of their power and heat-supply problem. This resistance is gradually—very gradually—breaking down under the lead of the very large industrials (steel mills, paper mills, chemical plants, and the like) who have found their power problems big enough to force the employment of specialists.

Still another factor affecting proper consideration of the subject is the accounting situation. It seems that many industrial accounting departments have lost sight of the fact that cost accounting is a tool for the use of production management, and consequently must be planned so that it will serve an engineering purpose, not degenerating into a string of figures a month late, precise to the penny, but inaccurate.

One of the outstanding difficulties in this connection is the almost general practice of lumping the investment in power and heat-supply equipment with the main plant investment, so that power and heat costs are only reported as operating and maintenance charges. As a result, when any new power project is up for consideration it must carry both fixed and operating charges in comparison with production charges only on the old equipment, and naturally the new project is often defeated if it is for savings alone. Only when more capacity must be supplied does the new plant get any of the consideration.

Power and Steam-Heat Relations

It is obvious that heat for process produced by the direct firing of any fuel has no effect upon the problem we are considering; but heat supplied as steam at any pressure has an enormous effect upon both power and heat cost. It is hoped, however, that by this time the older conception has died a natural death: namely, the assumption that because steam was necessary, power was obtained for nothing, or conversely, because power was needed, steam cost nothing. Actually, the cost of power is greatly reduced and the steam cost materially reduced, and both costs are easily and rigorously calculable.

It should be clear that the fuel charge for a turbine whose whole exhaust and bleeder steam goes to process should be based upon the relation:

(Heat equivalent of gross kw-hr. output) + (Heat equivalent of generator losses) + (Heat equivalent of mechanical losses) + Radiation

Based on 94.3 per cent full-load generator efficiency and 97.1 per cent full-load mechanical efficiency. The electrical losses for a 1500-kw. bleeder turbine will be 86 kw. and the mechanical losses 43 kw., both of them being substantially constant and unaffected by load. Therefore the heat equivalent of a kilowatt-hour is given by the expression $3413 \times [(\text{kw.} + 129)/\text{kw.}]$, which gives for a 500-kw. load 4290 B.t.u. and for a 1500-kw. load, 3700 B.t.u.

Similarly, for a 20,000-kw. machine having 96.8 per cent generator efficiency and 98.8 per cent mechanical efficiency the values are: generator loss, 640 kw.; mechanical loss, 240 kw.; heat equivalent of 1 kw-hr. at 1000 kw., 6410 B.t.u.; at 20,000 kw., 3560 B.t.u.

Total heat abstracted from steam for power, $H = 430{,}000 + 3413 \times (\text{kw.})$ for the 1500-kw. turbine, and $H = 2{,}940{,}000 + 3413 \times (\text{kw.})$ for the 20,000-kw. machine.

Since all heat not removed as work appears in the exhaust or bleeder steam, we are not primarily concerned with the engine efficiency if the bleeder requirements are larger than needed for furnishing the required power from the pressure drop available; but if the power requirements are large relatively to steam for process heat, both the engine efficiency and the initial steam conditions become primary factors.

The curves given in Dr. Kleinschmidt's paper of December, 1928, on "Balancing Heat and Power in Industrial Plants,"[2] are precise enough for all preliminary estimates. Figs. 1 and 2 reproduced from that paper show the available power developed between various initial and final pressures. There is a difficulty always present, however—namely, that of variation in balance, both of the actual from the estimated power and steam loads, and from the variations in output from the state of business affecting the whole load. It must be recognized that very few industrials are in a position definitely to assign steam quantities to each department, since this usually requires metering to an extent quite beyond the usual equipment; and further the steam meters as actually installed and used in many industrial installations are seldom closer than 10 in accuracy. Power distribution is easier to get, but there are still many plants in which the metering is very scanty.

Size Effects

Plainly the size factor affects the cost of power, and while the comparisons about to be considered are in general not for straight condensing plants, we are under the necessity of getting most of

[1] Mechanical Engineer, Stevens & Wood, Inc., New York, N. Y. Mem. A.S.M.E.

Presented at the Akron Meeting, Akron, Ohio, October 21 to 23, 1929, of The American Society of Mechanical Engineers.

[2] Trans. A.S.M.E., May-August, 1929, paper No. FSP-51-27.

the data from such sources since they are the only ones on a reasonably comparable basis. Even in these, however, the costs vary over a wide range. Considering only plants built from 1920 to 1928, and the majority from 1923 to 1926, an analysis of cost data from forty plants varying from 1000 kw. to 300,000 kw. in capacity shows some very interesting facts. Values for B.t.u. per net kw-hr. are the most consistent, and as shown in Fig. 3 vary from +18 per cent to —9 per cent from the average. Reducing the points from the actual capacity factors to 38 per cent capacity factor usually brings the points much nearer the average. Fuel cost can be easily plotted from this curve, the plot for coal costing $0.18 per million B.t.u. being given, and curves for coal at any other prices simply lines parallel to the B.t.u. line.

Fig. 4 gives the average operating and maintenance costs. For the sake of clearness, the points are omitted, but in the original plot, operating labor varied +100 per cent to —30 per cent from the average, fuel cost from +100 per cent to —50 per cent, maintenance +85 per cent to —100 per cent, and supplies from +250 to —55 per cent, while the total cost above fuel varied from +120 per cent to —55 per cent. These very large variations are not surprising when it is realized that the capacity factor varied from 17 per cent to 80 per cent, the average price of labor from $0.50 to $0.90 per hour, and the design of plant to such an extent that the number of operators in certain plants was twice that of others of the same size. All these variables except design of plant could be corrected by reducing costs to a standard capacity factor, and adopting a standard price for labor, but this is a task of some magnitude, and as the plots on logarithmic paper show the trend and averages much more clearly than cross-section paper, it was not thought worth while to make the corrections.

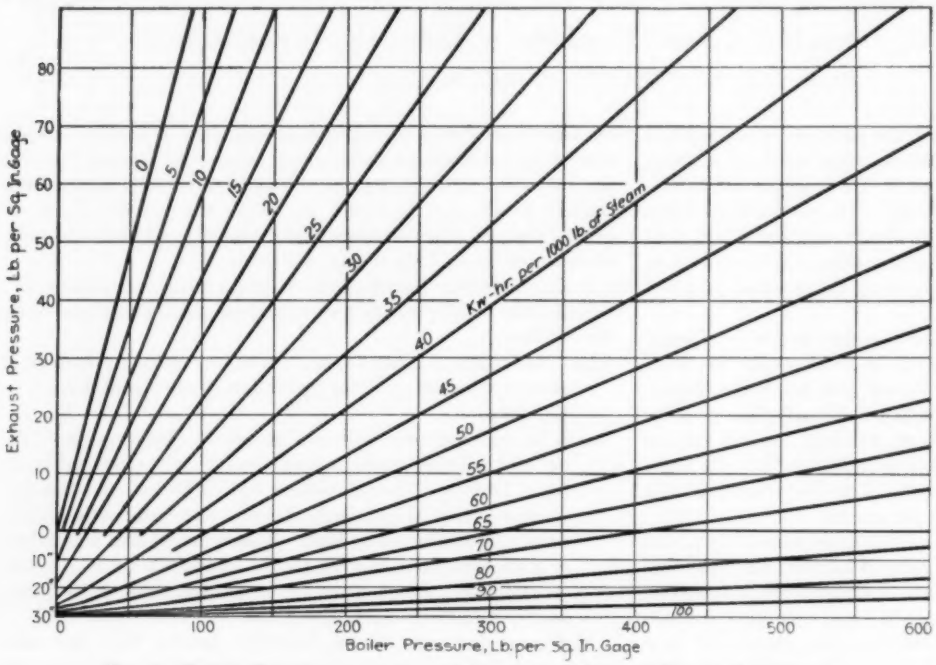

FIG. 1 POWER DEVELOPED BY IDEAL ENGINE FOR VARIOUS STEAM CONDITIONS

It should be remembered that straight-line plots on logarithmic paper represent curves on cross-section paper. One of the advantages of the logarithmic plot is that variations of a definite percentage either side of a line are lines parallel to the original lines whereas the same percentage variation on cross-section paper shows an increasing divergence as the numbers increase.

These curves may be used with safety for any good new design, as the costs are practically all on the low side for the newest plants, and tend to decrease year by year in new designs. It is noticeable that after capacity large

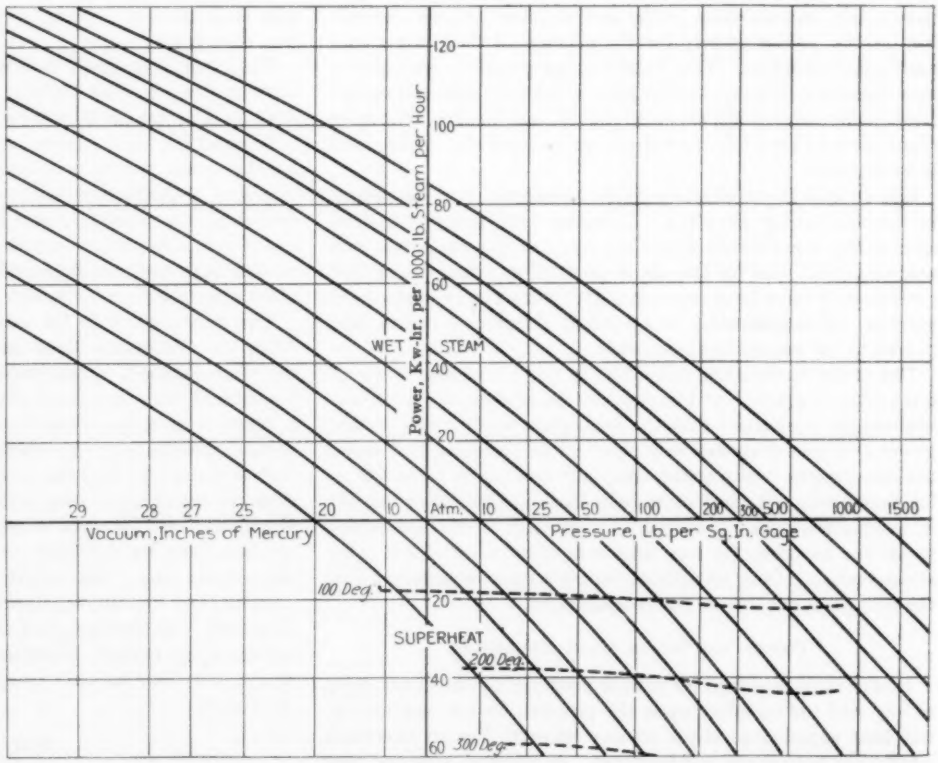

FIG. 2 POWER DEVELOPED FROM SUPERHEATED STEAM BY IDEAL ENGINE

enough to employ 30,000-kw. units is reached, there is little further decrease in B.t.u. rate, and not much more decrease in operating cost other than fuel; maintenance, in particular, is practically unaffected beyond an output of 150,000,000 kw-hr. per year.

While industrial plants (with the exception of steel mills) are not ordinarily interested per se in so large a plant as this, nevertheless these figures are needed to help determine whether to build a new plant or buy power, since the question is usually one of whether to replace an inadequate, uneconomical industrial plant with a new and, for its size, economical one, or to buy power from a public utility. Naturally, as the public utilities grow at a rate which puts new units or new plants on their lines every year or two, the comparisons must be made with economical public-utility plants. It is worth noting that utility electric power is the only commodity which has steadily decreased in price during a period when everything else has risen.

Consideration of Fig. 5 shows that the efficiency of the turbine, exclusive of external losses such as those due to bearings, governor, oil-pump drives, generator losses, etc., decrease very slowly down to the 6000-kw. size, and only a little more rapidly below that size. It will be seen that the engine efficiency

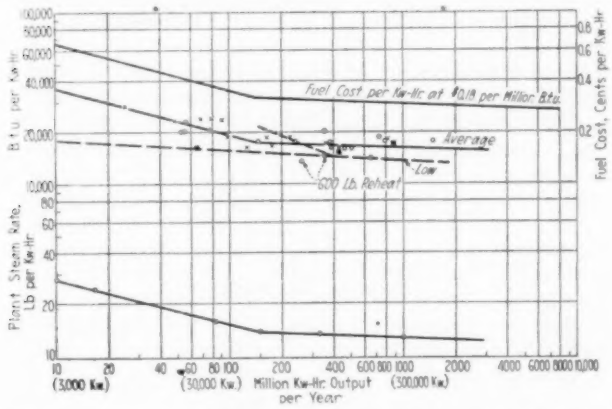

FIG. 3 B.T.U. PER NET KILOWATT-HOUR (FUEL COST AT $0.18 PER 1,000,000 B.T.U.)

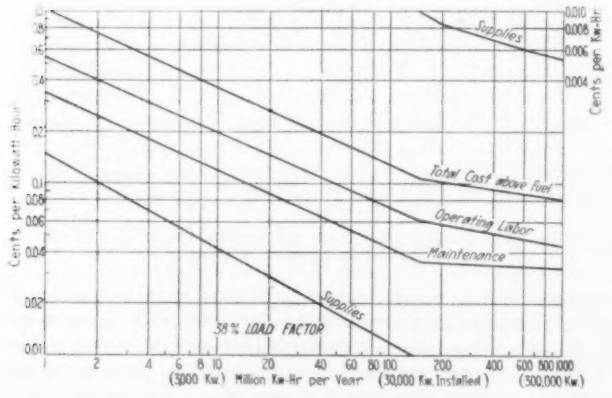

FIG. 4 COST OF POWER (PLANTS BUILT 1921–1928; COSTS, 1924–1928)

only falls from 80 per cent at 30,000-kw. capacity to 78 per cent at 6000 kw. and 48 per cent at 100 kw. The practice of thinking of turbine efficiencies in terms of brake output or, still worse, electrical output is undesirable as well as incorrect thermodynamically. Figuring on these bases gives erroneous steam flows and conditions. We are compelled to treat the external losses as part of the turbine output, so far as the steam is concerned. A single example will illustrate the force of this point. A 500-kw. back-pressure turbine has full-load mechanical and electrical losses amounting to 100 kw. For 400 lb. abs. (700 deg. fahr.) initial pressure and 160 lb. abs. back-pressure, the full-load steam would amount to 36,300 lb. per hour, the exhaust heat content would be 1296 B.t.u. per lb., and the efficiency 62 per cent. If figured on electrical output direct the exhaust quality would apparently be 1305 B.t.u., and the efficiency 51.7 per cent, the ex-

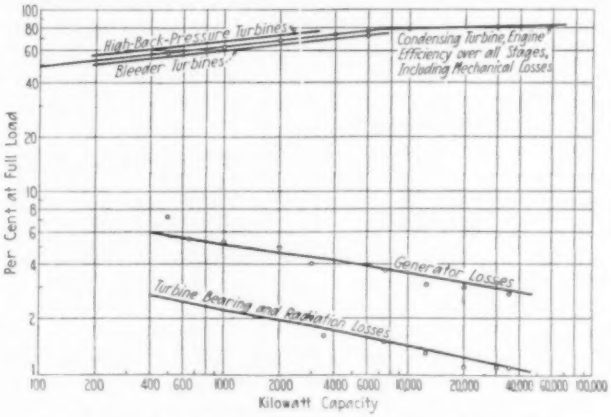

FIG. 5 TURBINE EFFICIENCIES AT VARIOUS OUTPUTS

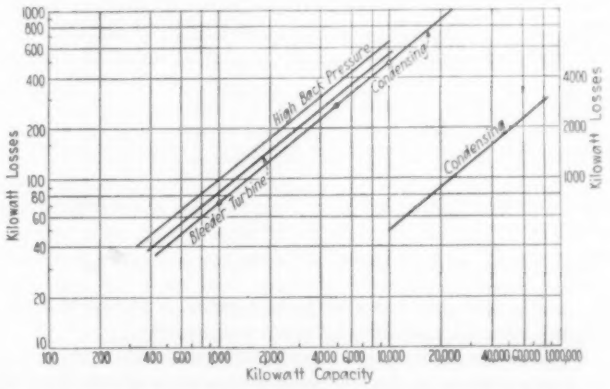

FIG. 6 TOTAL MECHANICAL AND ELECTRICAL LOSSES FOR VARIOUS TYPES OF TURBINE GENERATORS

haust heat in this case not being so far out. But at 100 kw. load the total steam required is 14,170 lb., efficiency 48 per cent, and exhaust heat content 1308 B.t.u. per lb. If figured on electrical output the exhaust quality would apparently be 1329 B.t.u. and the efficiency 25.5 per cent.

A further reason for using the method indicated is that it furnishes a reliable means of figuring the steam rates or total steam from no load to full load. The method is brief and convenient and is worked as follows: From the steam conditions selected, the adiabatic drop is taken from the Mollier diagram, the full-load wheel efficiency taken from Fig. 5, and the "indicated" steam rate then figured. Multiplying by the kilowatt load plus the kilowatt total losses from Fig. 6 gives the full-load steam. For no-load steam we merely take advantage of the fact that the no-load wheel efficiency varies only from 65 per cent of the full-load efficiency (Fig. 5) in a 500-kw. turbine to 70 per cent for a 30,000-kw. machine.

The no-load "indicated" steam rate is therefore simply the full-load indicated steam rate divided by 0.65 to 0.70, depending on the size. Multiplying this rate by the losses (which are not materially less at no load) gives the no-load total steam. The re-

mainder of the line is straight between these two points for all bleeder turbines, and up to the opening of the secondary valve for straight condensing machines. Bleeder or back-pressure machines are generally built without secondary valves, as bypassing stages is usually not feasible on account of interfering with the bleeder points.

The engine efficiency of back-pressure turbines is higher than that of straight condensing turbines not only because the wheels are much larger but because the work is all done in the high-pressure and superheat region and the stages are more efficient. But the turbine mechanical losses are higher, as the machine has

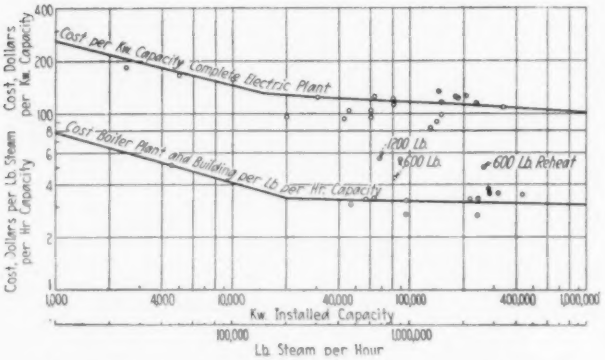

FIG. 7 INVESTMENT COST, STEAM AND ELECTRIC PLANTS

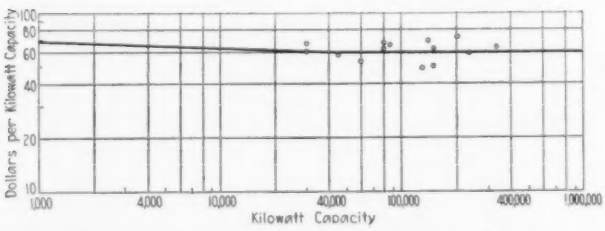

FIG. 8 INVESTMENT COST, ELECTRIC PLANT INCLUDING BUILDING

the weight and dimensions of the high-pressure portion of a condensing machine averaging 2.5 times the capacity.

The bleeder turbines are lower in efficiency than normal condensing ones because the low-pressure stages are always designed for full flow to develop the output with no bleeding, but are nearly always much underloaded in actual operation due to bleeding. The efficiency of these stages is of course lowered considerably, and as the high-pressure end is increased in size the no-load curves are also increased an average of 1.5 times. Fig. 6 is convenient for taking off the losses.

INVESTMENT AND OPERATING COSTS

Plant investment costs vary not only with size but with design. It may be definitely assumed, however, that with present experience with different designs the costs may be kept on the low side. The largest variables are foundations and building structures; the former is to a great extent determined by the character of the ground, the latter partly by the character of the design and partly by the architectural features. For industrial purposes it may be taken for granted that all architectural cost effects will be very low—the building will simply be a casing for equipment; the same condition is also largely true for public-utility plants not located in large cities, such as New York, Chicago, and Philadelphia. Such location always forces the building cost up, and in general all labor costs, both for construction and operation.

The variation of cost per kilowatt for complete electric plants is given in the upper curve of Fig. 7. But in an industrial plant the boiler equipment is generally very much larger per kilowatt of electric capacity on account of the increased steam rate due to bleeding or back-pressure service, and in many cases because of additional direct steam load for manufacturing service. The investment and operating costs for straight electric plants, therefore, cannot be used directly for estimating results in an industrial plant, but they do at least provide the data from which may be obtained the necessary separate information on steam-generating and power-generating sections of the industrial plant.

The data from half the plants investigated was in shape to separate boiler-room and turbine-room costs. The first information needed, that of boiler-plant cost, including the necessary building, is plotted in the lower curve of Fig. 7 against steaming capacity installed. Similarly the cost of the electric equipment, including its proportion of building, is plotted in Fig. 8. The values in Fig. 8 must be used with caution, as the back-pressure

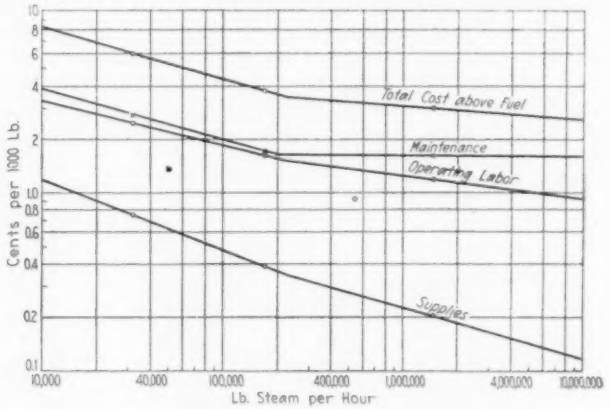

FIG. 9 COST OF STEAM PRODUCTION, INCLUDING BUILDING MAINTENANCE

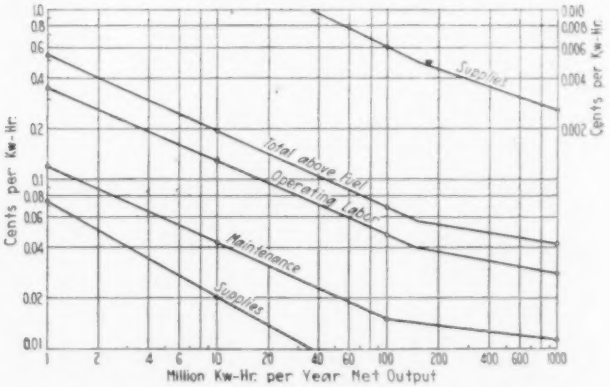

FIG. 10 PRODUCTION COST OF POWER ONLY (BUILDING MAINTENANCE INCLUDED)

turbines, and especially bleeder turbines of more than one point bleed, are more expensive and the costs will rise to some extent.

The operating costs have similarly been split into steam generation and power generation, each including a proportionate building maintenance (small in any case), and are plotted in Fig. 10. With the foregoing data we have the means of estimating with good accuracy almost any kind of industrial set-up. One other variable must be covered, namely, load factor. In all the curves given in Figs. 3, 4, 9, and 10 the costs given are for plants averaging 38 per cent capacity factor, the latter being defined as

$$\frac{\text{Net kw-hr. per year}}{\text{Installed capacity in kw.} \times 8760}$$

The variations of cost with capacity factor are rather hard to pin down, as the only published data are the studies of E. H. Scofield accompanying the A.E.R.A. Prime Movers' Committee Report of 1915, some of his more recently published figures, and some data on the Boston Edison plant. Calculations on a number of plant performances for design purposes corroborate these data and show that within reasonable accuracy the total operating costs in a given plant vary as shown by a line inclined at 20 to 22 deg. to the horizontal on log paper (see dotted line in Fig. 3), or in other words, total operating costs vary as the 0.76 power of the kilowatt-hour output. With this rule of variation it is easy to interpret costs for other load factors.

Industrial Installations

A few actual set-ups may be of interest. The first is a large foodstuff and beverage plant. When the problem of more capacity came up, the plant consisted of 26 boilers in sizes from 350 to 438 hp. in two boiler houses, two vertical-compound-engine generating plants, and one Diesel plant aggregating 2500 kw. capacity. The loads are rather steady all week, the only power shutdowns being on a few holidays, and partial load on Sundays. The steam demand reaches 200,000 lb. per hour at 140 lb. pressure, with average of from 90,000 to 120,000 lb., 20,000 to 40,000 lb. process steam per hour at 30 lb., and 40,000 to 60,000 lb. per hour at 5 lb. The electrical peak is 2500 kw., 1800 kw. being the average. The difficulty in choice of new equipment lay in the fact that large changes in the various kinds of product will likely take place, and considerable electrification of present steam drives is desirable (ice machines, pumps, and compressors). Consequently the tendency will be for electric load to go up at a much greater rate than steam demand, and there may even be a reduction in the latter.

The boilers vary from 20 to 40 years in age, so that complete replacement in any case is necessary. The firing equipment is all chain-grate natural-draft, burning a particularly difficult coal, running about 10,000 B.t.u. per lb. containing up to 16 per cent moisture, 20 per cent ash, and 3.5 per cent sulphur, and having an ash-fusion point of 2100 deg. fahr. The boiler efficiency has been about 60 to 62 per cent and could not be much improved in the present equipment.

The new plant will consist of three 10,760-sq. ft. 450-lb. (625 deg. fahr.) boilers with water walls and pulverized-coal firing, and two 2500-kw. bleeder turbines. Space is available for an additional boiler and turbine. The bleed point is 140 lb. gage and the back pressure 5 lb. gage. The demand for 140-lb. steam for old engine drives is so large that there is more than ample steam to supply the power still leaving from 20,000 to 50,000 lb. to be dumped into the 140-lb. mains through a reducing valve. The 30-lb. steam is supplied, as before, from the 140-lb. mains through a steam accumulator. The cost of steam with $2.90 coal will be approximately 26.46 cents per 1000 lb. and of power, 2.430 mills per kw-hr. The fixed charges for steam will be 7.54 cents per 1000 lb. and for power (including a proportion of the steam-plant fixed charges) 3.514 mills per kw-hr. The total costs are then 34.00 cents per 1000 lb. of steam, and 5.94 mills per kw-hr. for power. Obviously the situation is so favorable to industrial power generation that public-utility power could not compete except under a condition discussed below. A limited breakdown connection with the public utility is provided, but no regular power use. The reduction in cost over present operation in this industrial will pay a return of about 25 per cent on the investment, particularly as one of the old power-house buildings was remodeled for the new equipment at a lower cost than that of a new building.

Another plant manufacturing artificial silk was faced with a somewhat similar problem, but in this case the expected increase of production required steam and power in about four times the former quantities. The old plant consists of one small turbine generator and a turbine-driven refrigerating machine. The steam load is so large relative to power that even with as low a pressure as 250 lb. (550 deg. fahr.) there will be live steam to the extent of 30,000 lb. per hour reduced in winter, but an even balance in summer. The new plant would be made up of three 1500-kw. turbines bleeding a small amount at 140 lb. for heaters and evaporators (30 per cent make-up exhausting to the 15-lb. system), 15 lb. back pressure, and three 6500-sq. ft. boilers. The steam demand 24 hours a day 7 days a week for 7 months is 131,000 lb. per hour and 124,500 for 5 months, all the 15-lb. steam from the evaporators and turbines being used to heat 2500 g.p.m. of hot water and other mill process. The heat balance is arranged so that by shifting load between the heater condenser on the turbine exhaust and the mill heaters, no steam is wasted, but in winter some must be put through a reducing valve to the 15-lb. system. The costs are 28.95 cents per 1000 lb. low-pressure steam operation ($4.55, 13,000-B.t.u. coal) and 7.15 cents fixed charges, or a total of 36.10 cents; and power, 2.26 mills operation and 1.37 mills fixed charges, or a total of 3.63 mills.

Another scheme of operation has been proposed several times in the last few years and offers much promise, although so far it has only been put into practice in one plant; that is, for the public utility to build a 1200-lb. station at the industrial, serving steam at anything up to, say, 250 lb. gage and such power as the industrial requires, and taking off whatever of the remaining power it requires for its own service. This power has the advantage of being available at peak, as distinguished from "dump" power, and is therefore much more valuable to the power company. The principal restriction is one of size, as the scheme cannot be applied to small plants directly.

The idea may work out for a group of plants, provided the distances are not too great, since the fixed charges on transmission of power and steam may determine whether the scheme is profitable or not.

As a matter of interest, the case of the beverage plant has been refigured for comparison. A 1200-lb. plant with a 10,000-kw. bleeder turbine is predicated; of course, no such plant has been built yet, but there is no reason to suppose that a small 1200-lb. turbine cannot be built in the future.

The estimated results are as follows: Same steam and power supply to the industrial, investment cost $1,800,000. The total net power developed is 9700 kw., of which 1800 go to the industrial. Production cost, 1.340 mills per kw-hr.; fixed charges, 1.105 mills per kw-hr.; total, 2.445 mills per kw-hr. Steam costs, 25.62 cents per 1000 lb. production; fixed charges, 9.36 cents; total, 34.98 cents. It will be seen that the power cost is lower and the steam cost slightly higher. But in the case of the 450-lb. plant, the total cost per year for power and steam is $569,900, whereas the cost from the 1200-lb. plant is $503,880 per year. In addition the power company has 69,300,000 kw-hr. per year at 2.445 mills per kw-hr.

There are four ways in which the industrial can plan its power and steam supply:

- *a* Complete plant, with suitable reserve, no utility connection
- *b* Normal-load plant, no reserve, public utility for excess power and reserve
- *c* Public-utility high-pressure plant, supplying steam and power to the industrial and furnishing excess power to its own lines
- *d* Purchase all power, and operate a low-pressure industrial steam plant.

The first two schemes may be desirable for plants having relatively low power and high steam requirements, and the choice between them can only be made for each individual case. The

third scheme will likely be desirable for large plants, or a group of plants close together, aggregating a large demand. The fourth scheme will generally apply only to the small plant with low steam demand relative to power.

It must be clear that there is no general solution for the problem of heat and power supply for industrials, as the permutations are endless. Every case must be solved for itself. The variables are: price of coal and labor, relative power to steam, load factor, investment, and operating cost as affected by size, and growth rate. As has been attempted in this paper, the best that can be done is to collect data which will give the engineer a reasonably assured basis for his calculations.

Discussion

BURT A. WALTZ.[3] In the work of the last year on the Mahoning Valley Sanitary District's problem of new water supply for Youngstown and Niles a steam pumping station and boiler-house development called for studies similar to those outlined in this paper.

In studying the designs of various modern boiler installations it was noted that various considerations result in designs involving wide variations in ratings of boilers.

Briefly, there now are boilers capable of operating as high as 500 per cent of rating, in round numbers. The method of developing such capacities is of course no mystery, but the use of unit costs for plants operating at widely varying capacities seems to introduce a factor which the paper does not recognize. The writer believes a discussion of the effect of boiler ratings upon unit costs would be of value.

EDGAR J. KATES.[4] The paper, while up to date as regards the characteristics of steam-power equipment, fails to take account of the Diesel engine's place in the power scheme.

The closing pages of the paper state the four ways in which the industrial can plan its power and steam supply. The last case, that of the small plant with low steam demand relative to power, is sometimes much better served by Diesel power than by purchased current. Purchased power is generally not cheap in the small plant, whereas Diesel power is, because the excellent fuel economy of the Diesel engine is obtained even in the smallest sizes and because Diesel attendance costs are low. Consequently, Diesel power often costs less than purchased power in small plants, and Diesel-engine reliability is no longer questioned.

Furthermore, it is quite practicable to utilize at little expense much of the waste heat discarded by the Diesel engine in the jacket water and exhaust gases. Where this is done, the fuel consumed in the coordinating low-pressure steam plant is correspondingly reduced, and if the heat demand is small relative to power, the fuel-burning plant may be entirely dispensed with.

Careful studies of cases such as these will frequently show that the Diesel power plant will supply power and heat at a considerably lower cost than either steam-power equipment or public-utility power together with low-pressure boilers.

R. R. JONES.[5] The author makes a statement to the effect that few plants, with the exception of steel mills, would be interested in a plant as large as 30,000 kw. or producing 150,000,000 kw-hr. per year. From this the writer takes it that the power requirements of factories producing rubber goods are not as fully understood as they should be. There are in this locality at least three such factory power plants whose sustained peaks are in excess of 30,000 kva. and whose annual production approaches 200,000,000 kw-hr. a year. Indeed, there are but few industries in which the subject of power and heat are so important as in the rubber factory.

The industry is also a large user of steam. In fact, the steam load for process work is, assuming the power is generated in a modern condensing plant, rather greater than the steam required to generate the power. Using a concrete example, if a Ford or similar small tire requires for processing 95 lb. of steam, it also requires for mechanical fabrication about $6\frac{1}{2}$ kw-hr., or a ratio of 1 kw-hr. to 14.6 lb. of steam. While the steam load required for the process work has been slowly declining from year to year, the electric power required, either directly applied or indirectly in the form of compressed air, water, etc., has been increasing and probably will continue to do so for some time. That this increase represents a healthy condition may be shown by the examination of production sheets of ten years ago and of the present time. If the power consumed per man per month ten years ago and the production in pounds during the same time are compared, they bear a ratio of about 1 to 1, while at the present time the ratio is about 2 to 3. That is, if a man used 1 kw-hr. to produce 1 lb. of product ten years ago, he now uses 2 kw-hr. and produces three units of goods. This trend is observed, of course, not only in the rubber business, but in all lines and is one of the reasons why the subject of industrial power is justly receiving so much attention.

Using the figures previously mentioned, of the ratio of steam for process to steam for power, brings the interesting conclusion that, if the process-steam load and electric load were synchronized and some cycle of high pressure working could be devised that would give a steam rate per kilowatt-hour of 14.6 lb. and still leave the steam in proper condition for process work, the rubber industry could generate all its power as a by-product. This conclusion would seem to point to another, and that is that most industrial plants should be considering some high-pressure cycle as a means of reducing their power costs.

There is some confusion among non-technical men resulting from the published statements of the results obtained at various boiler pressures by the utility companies and the great lack of uniformity in the selection of boiler pressures by them, but the writer thinks this can easily be explained by calling to their attention the small increase in thermal efficiency with increase in pressure, operating condensing as against the large increase in kilowatt-hours per 1000 lb. of steam when working non-condensing, as the initial pressures and temperatures are increased. If there is anything that just fits the case, it is the high-pressure non-condensing combination in an industrial plant using large quantities of process steam. And it may be shown equally well that this applies to the smaller as well as the larger, having due regard to the fact that each case is a problem in itself.

The fact that the steam requirements and electric demands are not or may not be synchronous indicates that the full advantage of high back-pressure working may not be realized unless such plants operate in parallel with condensing units located in the same plant as the non-condensing units or that the industrial plants operate in parallel with a utility. This combination of a high-pressure industrial plant and a utility is theoretically the best combination for an industrial plant not already equipped with an efficient condensing plant, but practically it does not always work out that way, because the usual rate sheet of a utility is not developed with that end in view.

The fact that the industrial with its high-pressure plant can make a portion of its power cheaper than can the utility and that the utility can probably make the remainder cheaper than can the industrial indicates there is room for both, and with proper cooperation in the making of rates both can profit.

In general, it will be found that all or any fraction of the load of a factory making rubber goods is a desirable load. Usually the load factor is extremely high, and the power factor is held as near unity as possible. The load is much more constant than a railway load, and this constancy can and possibly will be improved by the use of steam accumulators or other means.

WILLIAM F. RYAN.[6] The paper gives much useful information in a most usable form. The charges assumed for heat energy can be readily corrected to any basis of accounting, and it is no criticism of the paper as a whole to point out that method of cost accounting is not applicable in many industries.

The author charges the consumer of steam the same price for a heat unit, whether it is delivered at 700 deg. fahr. or at 100 deg. fahr. For many processes this system is fair enough for all practical purposes, but in others it is wholly unfair and would discourage the use of exhaust steam.

Even in such a simple process as heating a building a heat unit is worth more at high temperature than a heat unit at low temperature. In more complicated processes, such as multiple-effect evaporation, the value of steam is as much a function of saturation temperature as it is of heat content.

For a concrete example, consider a chemical plant generating steam at 150 lb. gage pressure and operating non-condensing turbines which exhaust at 10 lb. gage. The exhaust steam is used for the concentration of a salt. On the author's basis of cost accounting the consumer of exhaust steam would be charged about 85 per cent of live-steam value. Yet live steam can be used triple effect where exhaust can be used only double effect; in other words, it takes 50 per cent more exhaust steam than live to produce the same result. Obviously the supervisors of the concentrating operation would resist the use of exhaust steam at 85 per cent of live-steam cost when it has only 67 per cent of live-steam effectiveness.

It would be uneconomical for such a plant to generate power in condensing turbines and to supply live steam to the evaporators, but that result might eventuate if the consumer is not offered some incentive to use exhaust steam.

It is an almost general principle of cost accounting to base charges on cost of production. Why should exhaust steam be an exception? In the type of plant under discussion exhaust steam is as much a "product" of the power station as is electric power. What does it cost to produce exhaust steam?

In the chemical plant used as an illustration, the turbines take steam at 150 lb. gage pressure with moderate superheat and exhaust at 10 lb. gage. The water rate is about 35 lb. per kw-hr. If no exhaust steam were sold, but the heat in the steam were utilized to the fullest possible extent in power product (that is, by the use of condensing turbines), then the water rate would be about 15 lb. per kw-hr. It follows that the power plant purchases 20 lb. additional live steam in order that it may deliver 35 lb. of steam to the process. Exhaust steam can be sold without loss if the producer receives 20/35, or 57 per cent, of live-steam value.

There are other factors in the "cost of production" of exhaust steam, but the additional live steam required is the principal expense. In the writer's opinion, no attempt should be made to reduce the cost of exhaust steam by taking into account the lower capital cost, lower maintenance expense, and lower auxiliary-power consumption of a non-condensing plant as compared with a condensing one. The cost-accounting system should offer some incentive to the producer as well as to the consumer.

In a plant producing a single product, division of costs between electric power and exhaust steam may be largely academic, and any system, rational or arbitrary, may suffice. In a plant where one product consumes most of the electric power and another product consumes most of the exhaust steam, it is extremely important that the cost of both forms of energy should be accurately determined.

AUTHOR'S CLOSURE

Referring to the remarks by Mr. B. A. Waltz in which he states that the use of unit costs for plants operating at widely varying capacities introduces a factor which this paper does not recognize, perhaps Mr. Waltz has not recognized that the operation of boilers at high ratings does not necessarily change the unit investment costs to any material amount. Whenever a boiler is designed to be operated at very high ratings, which implies low unit costs per kilowatt or per pound of steam for boiler surface, the situation also implies that much more heat-recovery apparatus is included to keep the overall efficiency high. It is the old question of whether one prefers to buy heating service in boiler tubes, economizer tubes, or preheater plates. As a matter of fact, experience has shown that in plants designed for high boiler-room efficiency in which the boilers are operated at average ratings varying from 190 to 600 per cent, the overall cost of the boiler-room equipment does not vary more than 5 to 10 per cent. This justifies the use of unit costs in the manner employed in the paper.

Referring to Mr. E. J. Kates' remarks, it is quite true that the paper did not discuss these Diesels, but in the space permissible for this contribution, not even the steam-power situation could really be adequately covered. There is unquestionably a large field in which the Diesel will ultimately be used, especially if it is developed for high speeds, so that the bulk and investment costs are not so great as at present. One point is worth noting, however, and that is that in the recovery of heat from Diesel-engine exhaust, it must be done by heating equipment of the economizer or preheater type in which the heat-transfer coefficient is very low. This of course raises the cost of the equipment for recovering a given quantity of heat. Furthermore, the amount of heat available in the exhaust of the Diesel engine due to its high efficiency is much less than that available from a steam turbine of the same output. Consequently, in many industrial plants it would be necessary to add steam boilers for process steam in addition to the Diesels. This in general will defeat the Diesel installation. The author is quite in agreement with Mr. Kates, however, that much more serious attention should be given to the possibility of Diesel-engine power for those plants where the heat balance is suitable for it.

Mr. R. R. Jones takes some exception to the omission of rubber plants from the big power and steam users' group. Attention should be called to the fact that few plants with the exception of steel mills can be considered 30,000-kw. power plants. There are not two dozen rubber-production plants in the country that use 30,000 kw. in a single plant, and compared to the total power plants in the country, this is relatively few. A few other large users can also be included if it is worth while specifying them—namely, pulp and paper plants, large smelting plants for copper, nickel, etc., and large chemical industries.

With regard to Mr. Ryan's remarks on the basis of charging for low-pressure steam, the author believes that he covered himself by showing that accounting within the industrial plant is still a completely unstandardized matter. For many purposes the author would modify the suggested method, which, however, would fit the majority of cases rather well. In those cases where the temperature of the operation puts the value on high-pressure steam greater than on low-pressure steam, of course some such weighting of the costs as Mr. Ryan proposes must be developed.

FSP-52-39

Recent Instances of Embrittlement in Steam Boilers

By FREDERICK G. STRAUB,[1] URBANA, ILL.

The author discusses briefly the cause of the recent boiler explosion at Crossett, Arkansas, attributing the failure to embrittlement produced as a result of using soda-ash treatment on a water too low in sulphate content. Other instances of cracking of seams in steam boilers are also described. Emphasis is placed upon the regular inspection of leaky seams in steam boilers, particularly when the boiler water does not meet the A.S.M.E. recommendation.

AS A RESULT of the explosion of one of the boilers in a power plant at Crossett, Arkansas, during May, 1929, the question has been raised as to how much attention must be given to the examination of boilers in order to prevent explosions of this nature. Data have been gathered in regard to steam boilers which have been badly cracked, as well as from those which have actually exploded. These data have been gathered through the courtesy of the boiler manufacturers, the steam-boiler insurance and inspection companies, and various operating companies whose boilers have cracked.

All of the instances of cracking which will be discussed are typical instances of embrittlement cracking. The criterion of whether embrittlement cracking has occurred is the manner in which the cracks proceed through the steel. If the small incipient cracks are truly intercrystalline and the metal is good in all other respects, it is felt that the cracking may be classed as embrittlement. One must realize that an examination of a large crack where the plates have started to pull apart will reveal transcrystalline failure. Also, where cracks have not started the plate will have regular slip lines and will experience transcrystalline failure when subjected to stress. Embrittlement cracking is caused by chemical weakening of the grain boundaries, and where the weakening has not taken place the plate is normal. If the weakening progresses far enough, static failure (transcrystalline cracking) will naturally occur due to overloading of the weakened plate.

The boiler plant at Crossett, Arkansas, consisted of six 500-hp. boilers operating at 215 lb. pressure. The boilers were about six years old. During the first two years of operation the make-up water was taken from a pond and received no treatment. Because of dirty steam and some scale, a system of treatment was started using a deconcentrator in connection with soda ash, and this method of treatment had been in use about four years when the explosion occurred.

Boiler No. 6 exploded. The seam opened up the entire length of the drum and both heads blew out. Boiler No. 5 was knocked out of its setting and badly damaged. When the remaining boilers were subjected to hydrostatic tests, they were found to be badly cracked. The cracking took place from rivet hole to rivet hole in the riveted areas. Examination of the fine incipient cracks showed them to be typical embrittlement cracks.

The boiler water was analyzed daily for alkalinity, but no attention had been paid to the sulphate content, which was decidedly low.

In addition to the Crossett explosion, data are available in regard to embrittled boilers in the following locations: Virginia, Ohio, Michigan, Louisiana, New York, Colorado, and Minnesota. The main data in regard to these plants are as follows:

Virginia. Three 500-hp. water-tube boilers operating at 425 lb. pressure cracked after two years of operation. A crack opened up in one boiler for a length of over 7 ft. from rivet hole to rivet hole, as shown in Fig. 2. Rivet heads cracked off and

FIG. 1 POWER PLANT AFTER BOILER EXPLOSION

cracks were found in all three boilers. The small cracks were found to be typical embrittlement cracks.

The make-up water came from a well and was not treated. It contained a large amount of sodium carbonate and very little sulphate. The boiler water was analyzed daily for alkalinity, but no record was kept of the sulphate content.

Ohio. Four 722-hp. boilers operating in Dayton at 145 lb. pressure were found to be badly cracked after one year's operation. The cracks occurred in practically all the seams of the drums. The boilers were in a dangerous condition when the cracking was detected. Tube ends were also found to be badly cracked. The cracks were typical embrittlement cracks.

A well water was used for make-up water, and was zeolite-treated before being fed to the boilers. The sodium carbonate

analyzed weekly. The results of these analyses gave the following information:

Ratio $\frac{Na_2SO_4}{\text{Total alkalinity}}$	Portion of the three years
Below 1	14 per cent
Between 1 and 2	32 per cent
Between 2 and 3	32 per cent
Above 3	22 per cent

The phosphate content was zero at times, and high at other times. The cracks were found to be intercrystalline and could be readily classed as embrittlement cracks.

Minnesota. One 500-hp. boiler operating at 200-lb. pressure had been in operation on zeolite-treated river water for about seven years. The insurance inspector notified the operators about the danger of embrittlement because of the high causticity in the boiler water, at least two years before the cracking occurred. The operators asked the water-treating company about the possibility of danger and were told that no trouble would result from the use of their treatment. Consequently no attention was paid to the sulphate content. The boiler developed serious cracking, and only timely examination by the cautious inspector saved an explosion. The cracking was found to be typical of embrittlement cracking.

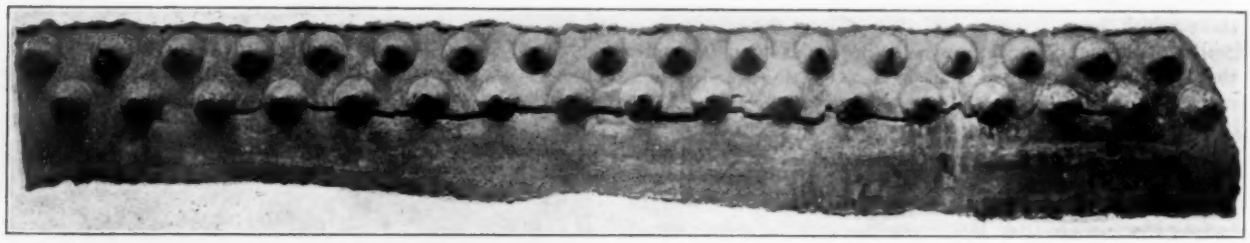

FIG. 2 EMBRITTLEMENT CRACK IN MAIN PLATE OF 425-LB. BOILER

content was high in respect to the sulphate content. A high caustic alkalinity was carried in the boiler water.

Michigan. Three 500-hp. boilers being operated in Pontiac at 150 lb. pressure were found to be badly embrittled. The boilers were five years old. For three years the water treatment used gave a high sulphate and low caustic content in the boiler water. The water treatment used during the last two years reversed this condition and gave a water which did not meet the A.S.M.E. Boiler Code recommendation. The cracks were found to be typical embrittlement cracks.

Louisiana. Rivets were found cracked off from the boilers after four years' operation at 200 lb. pressure. No straps were removed and no cracking could be detected in the plates by means of an external examination of the boilers. The rivets were found to have cracked in an intercrystalline manner.

The water in use was a well water practically free from sulphate and contained sodium carbonate.

New York. Two 500-hp. boilers were in operation at this plant. The steam pressure was 175 lb. One boiler had been in use one year on hard water before the second boiler was installed. At the time the newer boiler was installed, a hot-process lime softener was put in operation. The resulting boiler water was low in sulphate and high in causticity. After seven years' operation, sixteen rivet heads were found cracked off from the inside of one of the seams of the newer boiler. When the butt straps were removed they were found to be badly cracked. The cracking was typical of embrittlement cracking.

Colorado. Serious cracking was detected in a 1300-hp. boiler operating at 380 lb. pressure. The boiler was three years old. A fairly pure make-up water was used and soda ash treatment was given. At times sodium sulphate, phosphate, and tannin were used. A composite sample of four boilers had been

Other cases are on record, but these serve to show clearly that various types of boilers operating at different pressures are encountering embrittlement. The only factor common to all boilers is the occurrence of high causticity in the absence of sufficient sulphate content. This boiler water did not meet the A.S.M.E. recommended ratios for the prevention of embrittlement.

The data from the embrittled boilers cited show that the cracking took place in boilers made by practically every large boiler manufacturer. It also occurred in seams subjected to high temperature differentials as well as those entirely away from the heated areas. Boilers receiving excellent fabrication cracked just as rapidly as those not so well made.

Most of the cases were detected before it was too late as the results of timely inspection. A few had reached the dangerous stage, due to the fact that no attention was paid to the type of water in use. It was not realized that waters not embrittling in nature may be readily made so by certain methods of water treatment.

Emphasis should be given to the section of the A.S.M.E. Boiler Code which reads: "Pending further operating data from boilers in service, it is recommended that the requirements of Pars. 1–44 of Section VI of the Code be extended to all riveted seams, and that careful examination of all seams be made if leaks occur and do not remain tight after calking."

Discussion

H. A. ROBBINS.[1] The author is entitled to a vote of thanks

[1] Superintendent of Power, Brooklyn-Manhattan Transit Corp., Brooklyn, N. Y.

for keeping this matter before the public. In the earlier years there appeared to be a tendency to keep under cover cases of hydrogen embrittlement, as it was then spoken of, caustic embrittlement, embrittlement, or cracking. This possibly was due to the fact that those who had experience did not feel that they knew enough about the subject to start a general discussion.

In 1917 in one of our plants, equipped with 72 650-hp. boilers operated at 200 lb., trouble was experienced with leaking girth seams and rivets, which could not be made tight by calking. The boiler company was called in and a thorough inspection was made of every boiler in the plant. It was necessary to replace drums or sections of drums on approximately a dozen boilers.

The first idea of course was that the quality of the steel or the manufacturing methods were at fault. However, it was found later that the trouble could at least be avoided by the proper treatment of the feedwater. Water conditions were such that caustic soda and soda ash had been used for a number of years. Records showed that the NaOH had exceeded the Na_2SO_4. Following the discovery of the troubles we were advised to carry the Na_2SO_4, equal to or higher than the NaOH, which we have continued to do.

Although no repetition of the trouble has been experienced we are now endeavoring to bring the boiler water closer to the ratios recommended by the A.S.M.E. for prevention of embrittlement.

ALPHONSE A. ADLER.[3] The author assumes that intercrystalline failure of boiler plate is the criterion for caustic embrittlement. This may be so, but it is not conclusive. It is possible that the weakening at the grain boundaries may be due to other causes, and before general acceptance more proof should be obtained that nothing but caustic embrittlement could bring about this condition.

Any complete investigation should study not only the effect of boiler water used but also the previous history of the manufacture of the boiler plate, its fabrication into finished boilers, and the general design of riveted joints. Assuming that the steel is of exactly the same grade as was used before caustic embrittlement received attention, there are other factors that should be considered.

Soon after the meeting at which this paper was read the writer had the opportunity to inspect a piece of the seam which was reported to have come from one of the exploded boilers mentioned in the paper. The workmanship of the specimen was not up to standards required in good riveted-joint design. Some of the more important items to which attention is directed are:

1 A design in which the stress between rivet holes is the same in both boiler and cover plate to insure equal deformation under stress and insure uniform loading of rivets.

2 Adjustment of rivet-driving pressure to insure absence of initial stress on completion of riveting. (It is conceivable that rivet pressures may be so high that a seam may crack without bursting pressure in the boiler.)

3 A strictly uniform pitch of rivets to insure uniform deformation under stress between rivet holes.

4 Accuracy in driving rivet shanks normal to the plate surfaces to prevent tension components in the rivet.

In addition to the foregoing it is suggested that an investigation be made as to the effect of the injury due to the cold rolling on boiler plate especially in the heavier sizes.

JOHN HUNTER.[4] As a supplement to the investigation and conclusions on caustic embrittlement published by Professor Parr and F. G. Straub in Bulletin No. 177 of the University of Illinois, the paper on "Recent Instances of Embrittlement in Steam Boilers" is of great value in calling attention to the possibility of this condition arising, by citing definite instances where it has recently occurred. Those interested in the design, manufacture, and operation of steam boilers, especially with the wider use of higher steam pressures and temperatures, are fortunate in having at hand the results of such an important investigation and study of this subject, so vital in its relation to the safety of human life and property, relating to the cracking of boiler plates at the riveted joints, commonly known as embrittlement. By accepting and using the conclusions resulting from this investigation, published in Bulletin No. 177, serious accidents will be averted.

It has been the writer's privilege to investigate actual cases of the occurrence of this condition of embrittlement in boilers. A serious case was encountered in 1922 at one of the boiler plants in Dallas, Texas, where five boilers of the bent-tube type were condemned on account of cracks in the lower drum plates between the doubling plates, which had been removed for inspection. These cracks extended nearly the length of the drums and ran longitudinally between the rivet holes, with star cracks radiating therefrom similar to those shown in Mr. Straub's paper. In the same plant new drums were being installed in a longitudinal-drum boiler, replacing drums removed following cracking of the same nature. These boilers had been in service from four to eight years.

An investigation of feedwater in this plant, which was obtained from wells, indicated a high concentration of caustic. Although but little was known of the subject at that time, the conditions in this plant seemed to follow very closely those where similar failure had occurred in boilers of a scout cruiser in the U. S. Navy, and it was concluded that the cracking in this instance was due to caustic embrittlement resulting from the nature of the boiler water. Inquiry in other plants in Dallas, which were using city water in place of well water, showed that similar trouble had not been experienced.

In further investigation of this subject, the writer was called to Houston, Texas, in August, 1922, to examine a boiler that had developed steam leaks. The boiler was of the longitudinal-drum type of 1000-hp. capacity, and had been in service for ten months, burning oil. External examination showed the fusible plug out of place. The fusible metal of the plug was later found perfectly intact at the bottom and inside of the drum. The brass body of the plug had been completely eaten away by the action of the boiler water.

Further examination of the steam drums disclosed several small leaks between the rivets of the circumferential joints, which when thoroughly cleaned on the outside uncovered cracks between the rivet holes in these circumferential seams in all three drums, extending from the water line on one side to the water line on the other side. In other words, on the surface of the joints covered by water, these cracks were found only on the outside landing of the joints. The boiler water at this plant had the same pronounced soapy feel as the water at the Dallas plant, previously mentioned.

TABLE 3 SUBSTANCES AS DETERMINED

Substance	Symbol	Grains per U. S. standard gallon No. 1 Boiler water	No. 2 Well water
Silica	SiO_2	0.35	0.70
Iron oxide	Fe_2O_3		
Aluminum oxide	Al_2O_3	0.13	0.08
Calcium oxide	CaO	1.70	2.56
Magnesium oxide	MgO	0.32	1.04

Total solution	77.30	27.93
Suspended matter	33.00	2.54

The well water contained sodium carbonate as a bicarbonate; also sodium hydroxide as a result of hydrolysis of sodium carbonate. Several sections of the boiler plate at the cracked joints were cut out and sent to the laboratory for analysis. These met the A.S.M.E. Boiler Code.

The workmanship on the joints was carefully examined and the rivet holes found true and well filled by the rivets. The plates were reasonably close together, and from general observation had not been abused in laying up the joints. The drums had been manufactured with the ordinary care. In ordering new drums for this boiler, directions were given the factory that all joints be calked on the inside to prevent any possibility of water getting between the plates, which under the existing water conditions seemed to be the cause of the plates cracking.

The study of feedwater treatment by those interested in this subject has developed means of taking care of the scale-forming matter, and at the same time avoiding the possibility of embrittlement, even with the higher steam pressures and temperatures. Their work should receive careful consideration and their recommendations should be followed closely. The requirement of inside calking on all drums or the use of seamless hammer-welded construction will furnish an additional safeguard. In the meantime the suggestion in the last paragraph of the paper, recommending careful examination of all seams indicating leaks for the possible existence of embrittlement cracks, should be followed.

J. C. McCabe.[5] It is assumed that engineers interested in steam boilers know that the external plate surface elongates and the inner surface shortens when rolled, about $1/2\ \pi \times$ plate thickness. It is evident that with plates of increasing thickness the structure of the steel plate is seriously disturbed if worked cold. In riveted joints of best design and workmanship rivets along the calked edge carry a load at the yield point in tension. These rivets have been strained beyond the yield point. The calking on plates of moderate thickness leaves the inside (dry side) of the plate in tension at the yield point and the outer surface in compression.

Observation of the rivet holes after the removal of rivets from a joint will give some conception of the enormous stresses set up in the best type of joint and the best workmanship. An examination of a riveted joint will disclose that the major stresses in the plate are not parallel to the calked edge. The major stresses or deformations are frequently about 45 deg. from the line of rivet centers. This condition can be best observed by constructing a flat joint.

Professor Straub has done a public service in calling attention to the hazard from a high concentration of sodium hydroxide. In Bulletin 155 on page 28, he says the following conditions must exist to induce embrittlement and cracking: First, "the actual stress must be above the region of the yield point of the metal; second, the concentration of the sodium hydroxide must be in excess of 350 grams per liter (350,000 parts per million, about 20,000 grains per gallon)." This would mean from 1600 to 1900 lb. of sodium hydroxide in a boiler of about 100 hp., if the concentration was uniform for the whole water content of the boiler.

A simple observation of the initial boiling point of this concentration in an open vessel and the rapid rise as the concentration increases will do much to impress men responsible for boiler operation. The recent practice of ascribing all cracking of boiler plate to embrittlement is far from the facts. In a calked riveted joint there is a condition with one side of the plate in tension and loaded to the yield point and the opposite side of the plate in compression at the yield point and usually the ligament between the rivet holes loaded to the yield point from the "barreling" of the rivet in driving. Why not attack the disease rather than the symptom?

Professor Straub lays much stress to the cracking around grain boundaries. He speaks of three boilers at Pontiac, Michigan, where cracked plates were found. The writer made an investigation of these cases and found the cracked butt straps exposed to the products of combustion, a temperature differential ranging from 60 to 80 deg. fahr., between the outer strap and the shell plates, and the rivet holes elongated from 0.010 in. to 0.016 in. girthwise. A micro photo showed that three out of four cracks were through the ferrite grain and the fourth partly around the grains and across the grains.

Observation indicates that in most cases of cracked plates the plate was loaded transversely as rolled. A plate so loaded is usually from 2000 to 10,000 lb. lower in tensile strength. This seems to be due to the elongation of the ferrite grains and throwing the grain boundaries more into parallel. The writer would expect to find frequent cracks around the grain boundaries when loaded transversely as rolled in any case.

About one year ago the lower drum of a Badenhausen boiler at the Ford Motor Company's Highland Park plant developed a crack of several inches on each side of a blowoff outlet which was also used for feeding water. A temperature difference of 150 deg. fahr. was found between the top and bottom of the drum. About $^2/_3$ the drum was in compression. The bottom $^1/_3$ was in tension and finally failed through the weakest section.

About the middle of November, 1929, a few heads were found broken off in the lower drum of a large boiler in the Rouge Plant of the Ford Motor Company in Dearborn, Michigan. This drum was 60 in. dia., the drum plates were $1^5/_{16}$ in. The heads were made of 1-in. plate. The heads were double riveted. A ligament of 70 per cent was left between rivet holes. A few cracks were found between rivet holes. This cracking was due to the stresses set up by temperature differentials in the shell plate. An area measuring $4^1/_2$ ft. girthwise and 23 ft. long was in direct contact with water at a temperature about 240 deg. fahr. while the balance of the drum was in contact with water at a temperature about 400 deg. fahr. The operating steam pressure was 250 lb. Two plates were used to form the drum. The butt-strapped joints in this case served as columns between the heads. The straps butted on both flanges. The load on the metal of the ligament at 250 lb. was about 5200 lb. This fact would not fit in the "caustic theory." The temperature difference was enough to strain up to the yield point with result-

[5] Chief Inspector, Department of Labor and Industry, State of Michigan, Detroit, Mich.

ant cracking at ligaments. The temperature differences will average about 150 deg.

It seems that our present knowledge of materials should enable us to design, construct, and use steam boilers without the misapprehensions of steam users of 75 years ago, who believed that explosions of boilers were due to an "unknown explosive gas" which formed in steam boilers and exploded without warning. It is now known that the old-time explosions were due to the poor slag-laden iron used.

It is about time to stop forming relatively thick plates cold and the construction of riveted joints strained, in part, to the yield point. These conditions are the cause of every so-called embrittlement crack. Why not recognize the value of fusion and forge welding under proper control as to fabrication and annealing? It is certain that the courts will give such recognition if the question is submitted regardless of codes or petty politics.

E. R. Fish.[6] There are few if any boiler manufacturers who have not been perplexed with serious cases of the cracking of plates in some portions of boilers of their manufacture. A good many will recall cases that happened many years ago for which no adequate explanation could be offered. The case is somewhat analogous to the physical troubles of the human body. Prior to certain developments of the medical science, people were afflicted with and died from ailments the nature of which was not fully understood, but which in the light of modern developments are readily diagnosed and treated. This has given rise to the statement by uninformed people that we are now subject to diseases that nobody had a few years ago. The diseases of course existed, but were not properly recognized.

While this theory of plate enbrittlement due to the presence of sodium hydroxide is to some extent controversial, the bulk of the evidence certainly justifies the theory that has been worked out. There is so much confirmatory evidence that most of us are convinced that it has merit, and until at least as strong evidence along other lines is presented, the acceptance of the embrittlement theory is fully justified. It must be recognized, however, that the factors at work are not fully understood and that there may be variations in the manifestations that are hard to reconcile.

The end that all are desirous of attaining is the adoption of means that will prevent this cracking which is a serious menace to the safety of high-pressure steam boilers. This means of prevention must, of course, be something that is reasonable and practicable, and this is the case with the means suggested in line with the embrittlement theory. Whether this theory is or is not ultimately disproved or still further strengthened, it behooves those responsible for the operation of boilers to follow the last paragraph in the paper, the epitome of which is, "Eternal Vigilance is the Price of Safety."

Alex D. Bailey.[7] So far in this discussion no one has had a kind word to say for the operating man who must live with these boilers which it appears are susceptible to so many baleful influences, and which may suddenly take a notion to rearrange the design of the power plant and the surrounding equipment as shown in the photograph in Professor Straub's paper. Of course the operating man, not being an expert, is apt to become confused and alarmed by the discussion of the chemists and the metallurgical experts who argue over his case and discuss the different ailments to which his equipment is liable to succumb. He is apt to think of the age-old definition of an expert and wonder if the tendency is not in that direction in this particular case. He has been running boilers for a long time and has never been blown up yet. He must remember, however, that steam pressures and temperatures are increasing, rates of heat absorption have increased by leaps and bounds, and with these changes, new problems have arisen in connection with the preparation and maintenance of proper feedwater and boiler-water conditions. Like other features of plant operation, the study of feedwater has become highly specialized.

The operating man may think he is in the position of the patient who, desirous of maintaining the spark of life and what little health he has left, calls in medical experts and diagnosticians for consultation. Each one of these is an expert on some particular disease to which the human body is heir, and it is only natural that each doctor should examine the patient for symptoms of the disease in which he is most interested and about which he knows the most. As a consequence there may be some discussion among the consultants and the patient will be scared stiff on being told that he may have any one or all of a number of deadly diseases. In conclusion, however, he will probably be told that by following a careful diet, being temperate, and avoiding over-exertion, he will live to a ripe old age, and if he is a wise patient, he will exercise all due precautions to preserve his health.

It seems that we in the operating field are in much the same position. It behooves us to listen attentively and to follow the advice of reputable professional men who have made this subject their life's work. Though they may disagree in detail, they are all working toward the same end, and in the final analysis they are all talking about the same thing, namely, the behavior of metals under stress, subjected to varying temperatures and pressures, and exposed to water containing various ingredients.

While it may be wondered why the experts apparently disagree regarding details, it must be admitted that discussions and differences of opinion are the basis of our progress, and that without them, we would rapidly get into a rut of complacent know-it-allness which would be deadly to advancement and hazardous to the safety of equipment and personnel. Discussions such as this are a healthy sign, and speaking for the operating man, the writer believes all should profit by them.

The fact that boilers, large and small, are continuing to fail, sometimes with considerable loss of property and even life, is sufficient warrant for each of us to consider his own case carefully, and to avail himself at every opportunity of the latest information pertinent to the subject. It is up to us to obtain the best professional advice, and to heed and follow carefully the admonitions and advice of those who have the latest and most up-to-date information on the subject.

R. E. Hall.[8] Without exception, the laboratories with which the writer is connected recommend that the concentration of alkalinity in the boiler water be maintained at the lowest concentration compatible with protection of the boiler surfaces proper. In a statement in the May 28 issue of *Power* we defined the limiting desirable concentrations of alkalinity in terms of hydroxyl radical. They may be restated here as pH values ranging from 10 on the low side to 11 on the high side with 11.5 as an extreme upper limit in cases in which high silica waters demand it for the maintenance of scale-free surfaces. It should be noted that the pH value of the boiler water making contact with the boiler should never be less than 9.6 measured on a cooled sample.

Maintenance of these low boiler-water alkalinities is fraught with effort. Several years ago before conception was had of

[6] Consultant, Boiler Engineering Dept., Combustion Engineering Corp., New York, N. Y.

[7] Superintendent, Generating Stations, Commonwealth Edison Co., Chicago, Ill.

[8] Director, Hall Laboratories, Inc., Pittsburgh, Pa.

any protective action of phosphate against embrittlement, we pointed out that through use of phosphate control of boiler water alkalinity became feasible, permitting maintenance of the recommended sodium-sulphate–total-alkalinity ratio in the boiler water at all operating pressures (Prime Movers Committee, N.E.L.A. Publication No. 256–71, p. 9, 1926), a thing impossible with soda ash as final conditioning chemical.

With the frequently changing fashions that are in these days being experienced in recommended sodium-sulphate–total-alkalinity ratios, any consistency of maintenance for those who attempt to keep pace with the prevailing mode is attainable only on the basis of extremely low and carefully controlled boiler-water alkalinity. In the ratio of sodium-sulphate–boiler-water-alkalinity a desired quotient may be obtained either by making the numerator (sodium sulphate) large or by making the denominator (boiler-water alkalinity) small. In our own work, we choose the latter alternative as inestimably the better practice since it represents greater safety to the boiler, better quality of steam, and greater economy of operation.

The present sodium-sulphate–alkalinity ratios are arbitrary. Agreement is pretty general that the efficacy of the sodium sulphate–alkalinity ratios in the boiler water in preventing deterioration of the boiler metal is due to the formation of a protective coating over the surface of the metal, especially in seams and elsewhere where concentration of the boiler water may occur. On this supposition, it becomes feasible to define exact ratios of sodium sulphate to alkalinity on the basis of the definite principles of solubility relations and concentrations involved at different operating pressures. Data are lacking or are uncertain at present above normal boiling temperature, but can be readily obtained. It would seem that there is no field open to investigation now which would give results of more value than that which would give definite information regarding the conditions in the boiler water necessary for the formation of films protecting the boiler metal from attack by the concentrated boiler water.

In Professor Straub's paper a number of very interesting cases of boiler-metal deterioration are added to those already described in his previous papers or those in conjunction with Professor Parr. As in the previous papers the effect of the specific chemical, caustic soda, is emphasized as fundamentally causative of deterioration.

The widespread interest in this subject among all those interested in boilers or their operation is attested by the numerous articles pertaining thereto that have appeared in the technical press during the year. Some of these agree that the cause of deterioration of the metal is chemical only, and especially due to caustic soda. Others, however, are looking to other factors as contributory, or primarily causative. It is notable in all these publications that attention is confined to boilers, although in many other fields there is accumulating a vast store of information relative to deterioration and cracking of metal. Cases of this character include the work of D. J. McAdam, Jr., of the Naval Experiment Station, Annapolis, Md.; H. S. Rawdon, Chief of Department of Metallurgy, Bureau of Standards, Washington, D. C.; T. S. Fuller, General Electric Company, Schnectady, N. Y.; and F. N. Speller, Chief Metallurgist, National Tube Company, Pittsburgh, Pa. In a paper to be published soon we shall discuss the bearing of the work of these various investigators on the question of boiler-metal deterioration.

Interest in and better acquaintance with deterioration of the boiler metal as evidenced by cracking, whether intercrystalline or transcrystalline, are calling attention to many examples of interest. Attention has been called to a case in which cracking developed in parts of a boiler, although the boiler water was practically neutral at all times, and the sodium-sulphate–alkalinity ratio therefore practically infinite.

Deterioration by cracking may occur therefore over a range of boiler-water alkalinities extending from zero as already noted to those high concentrations noted particularly in the Ohio and Louisiana cases cited in the paper under discussion. It is interesting in this connection to note that in the Ohio boilers, with total alkalinity of 3200, sodium sulphate of 710, and operating pressure of 145 lb., tremendous deterioration has developed in one year, while in the Louisiana boilers with total alkalinity of 3750, sodium sulphate of 5, and operating pressure of 200 lb., four years of operation had developed no deterioration detectable in the plates by external examination, except in some rivets.

One might expect, if alkalinity and sulphate are the sole or primary controlling factors in the deterioration, and if their effect is not subject to wide variation by reason of other contributing factors, that the Louisiana boilers would have shown by far the greater deterioration. The reverse is true, and it is extremely unfortunate that the analysis of the two cases has been limited to chemical considerations, when observations on the fiber stresses and various other characteristics of the boilers might easily have served to explain the anomaly.

The Crossett boilers are of particular interest inasmuch as exact data on the boiler waters of all six boilers are available over a period of years, and because of other significant features pertaining to them. Discussion thereof will be included in the report of a cooperative investigation of these boilers by the Naval Experiment Station, Annapolis, Md., and Hall Laboratories, Inc.

The following paragraph regarding the Crossett case occurs in Professor Straub's paper:

"Boiler No. 6 exploded. The seam opened up the entire length of the drum, and both heads blew out. Fig. 1 shows a portion of the plant after the explosion. Boiler No. 5 was knocked out of its setting and badly damaged. When the remaining boilers were subjected to hydrostatic tests, they were found to be badly cracked. The cracking took place from rivet hole to rivet hole in the riveted areas. Examination of the fine incipient cracks showed them to be typical embrittlement cracks."

The paragraph quoted is not in accordance with facts. The writer was present at the Crossett plant following the explosion and during the examination of the remaining boilers. The general manager of the Crossett plant states that no tests other than those of which the writer is cognizant had been made.

The facts in the case are that boiler No. 6 exploded. Disruption occurred along the seam of the lower drum of the two-drum vertical boiler and the heads blew out. The statements in the above quotation relating to character of cracking are presumably based on examination of samples from this boiler only.

Boiler No. 5 was displaced from its setting. As external examination of seams and rivets gave no evidence of cracking in this boiler, it was thought worth while to examine the seam on the lower drum, correspondingly exactly to the line of rupture in boiler No. 6. Accordingly the butt straps were removed for approximately three-fourths the length of the drum. Careful examination of butt straps, boiler plate, and rivets failed to reveal any characteristic cracking whatever. These observations with low-powered microscopes in the field will be checked, however, as a part of the cooperative investigation with the Naval Experiment Station mentioned.

Boiler No. 4, also displaced from its setting, was not examined or tested in any way.

Boiler No. 3, on hydrostatic test, blew out one head. The crack proceeded along the rivet line for some distance, then proceeded at both extremities by rupture of the head plate itself. Whether the boiler plate itself was cracked at all or not cannot

be stated at this time, but the condition of the metal will be reported on in the cooperative investigation.

Boilers No. 2 and 1 stood their hydrostatic test with no evidence of deterioration. Furthermore, three and four rivets in each boiler were removed along the seam (corresponding to that ruptured in No. 6) at points which by their appearance might attach suspicion to them. Examination of the cleaned exposed surfaces and of the rivets, as carefully as might be with a low-powered lens, gave no indication of cracking in these two boilers.

There is evidence, therefore, that two boilers of the six had cracked, and no more. We are justified in concluding that these boilers, all of the same type, have not all deteriorated equally, although subjected to like alkalinity conditions over a period of six years, and that other causative factors along with alkalinity have been determinative of failure.

Another consideration of interest applies to the Crossett case. Deconcentrators were used with these boilers starting in 1926. The chemical service obtaining with deconcentrators was for six months only. However, during the winter and spring 1928, the writer wrote twice to the Crossett plant urging the use of phosphate in conditioning the water, as its use would both lower the boiler-water alkalinity and also serve to give such protection from boiler cracking as lies in its power. No action was taken at the plant to carry these recommendations into effect.

The fact that success in water conditioning depends more upon exact chemical control than type of processing equipment led the Hagan Corporation about two years ago to abandon the deconcentrator, which was the focus around which our earlier investigations on water centered. The investigations originated for the deconcentrator provided the facts in the end that led to its discontinuance.

It is believed that the general phenomenon is the same whether cracking of the boiler metal occurs at zero or high alkalinity, and corrosion at stressed points, whether by caustic or other component in the concentrated boiler water, is one basic contributing factor. But as so aptly illustrated by the Crossett case, in which like operation and like boiler-water alkalinity in all boilers denoted equal opportunity for caustic corrosion in the seams of all, the rate of deterioration was not at all similar in the different boilers. The rate of deterioration of the boiler metal is dominated as well by other factors, prominent among which are the stresses, and in particular the cyclic stresses that are specific to the individual boiler and not common to all. When once erection is completed the stresses characteristic of each boiler are its irrevocable heritage.

The boiler metal, as furnished by the manufacturer, possesses an elastic and an endurance limit whose progress in the operation of the boiler is in one direction only, namely, downward. Corrosion accelerates this progress. Maintenance of protective films, integral with the metal, whether the oxide film of the boiler surfaces proper or a sulphate or phosphate film in the seams, by preventing corrosion, stays the downward progress. It seems logical to conclude that, beginning with its initial operation, every precaution should be taken to exclude from the boiler the processes of corrosion whether they be those of a neutral or a highly alkaline boiler water. The means of so doing are well recognized and definite.

Author's Closure

The subject of embrittlement has been under discussion so much during the last few years that any paper on this subject cannot attempt to cover all of its phases. The author, in preparing this article, made no attempt to discuss the entire subject. He felt that the interested parties were familiar with the conclusions reached in his previous publications (Bulletins Nos. 155 and 177, Engineering Experiment Station, University of Illinois; *Mechanical Engineering*, July, 1928, pp. 523-8). At no time has any attempt been made to infer that water alone was the cause of this difficulty.

The discussion which has been brought up illustrates very clearly that the whole question of embrittlement is a combination of stress and chemical attack. This has been the main conclusion of all the work which the author has conducted on this subject.

It is rather unfortunate that apparently a mistake has been made in reporting the exact details of the Crossett explosion. Since the author was not called to Crossett, but merely handled sections of the cracked plate which were forwarded to his laboratory, he had to rely entirely upon data furnished to him by the operators of the plant. The material reported is in accordance with the data furnished by the operators.

FSP-52-40

An Apparatus for the Determination of Creep at Elevated Temperatures

By A. E. WHITE,[1] C. L. CLARK,[2] and L. THOMASSEN,[3] ANN ARBOR, MICH.

This paper describes an apparatus designed for the purpose of measuring creep of metals at elevated temperatures. Due to the slight changes in dimensions encountered, such an apparatus must be sensitive to small variations. This particular machine is capable of measuring variations in length of the test specimen to about 2.8 millionths of an inch per inch.

The three essential parts of a creep-measuring apparatus are listed as (1) a means of applying and maintaining a constant load, (2) a means of obtaining and maintaining constant a given temperature, and (3) a means of accurately determining any deformation produced in the test piece. The manner in which this machine fulfils each of these conditions is described.

PRACTICALLY every one interested in the behavior of metals at elevated temperatures is now agreed upon the fact that at elevated temperatures, at least at those temperatures above a given fixed temperature, there is no stress below which a given metal will not continue to elongate or creep. The problem of determining safe working loads for a metal at these elevated temperatures therefore resolves itself not so much into one of determining the load at which no apparent creep would occur, but rather as the determination of the rate of creep for any given fixed load.

There is a wide range of permissible deformation allowable in the various industries. Some, as in oil-pipe still work, can allow elongations of the order of one per cent or greater per year, while in others, as in turbine manufacture, the permissible deformation is of the order of a small fraction of a per cent per year.

Even the relatively large rate of creep of 1 per cent per year involves only an elongation of 1.14 millionths (0.00000114) of an inch per inch per hour. If rates of creep of this magnitude are to be accurately determined it is necessary that either the test be conducted for long periods of time or else that an extremely sensitive measuring system be employed. As one is generally desirous of securing results as quickly as possible, the latter method is to be preferred.

A creep-testing apparatus has been developed at the University of Michigan which is capable of measuring elongation to 2.8 millionths (0.0000028) of an inch per inch on a 2-in. gage length. This machine is not claimed to be original in all respects, as in its design use has been made of ideas obtained from various sources. It is capable of yielding satisfactory results, however, and it is felt that a description of it might be proper at this time.

Contributed by the Joint Research Committee on the Effect of Temperature on the Properties of Metals, and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

DESCRIPTION OF APPARATUS

There are at least three essential parts to an apparatus to be used for the determination of the creep characteristics of metals at elevated temperatures. First, there must be some means for applying and maintaining a constant load; second, a means of producing and maintaining a constant temperature; and third, a means of accurately determining any change in the dimensions of the test specimen that may occur.

Loading Mechanism

A view of the creep apparatus now in use is given in Fig. 1, which shows the apparatus to consist of 5 individual units. A sketch of the side and front view of one of them is shown in Fig.

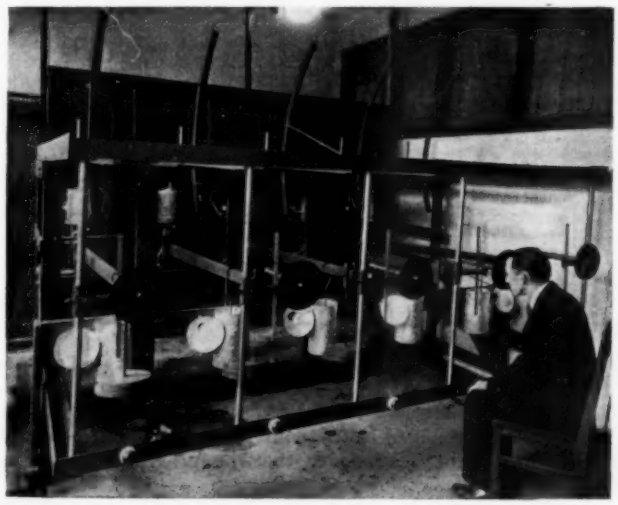

Fig. 1 Apparatus for Determining Rate of Creep of Metal

2. The loading device consists of a lever F pivoted at one end and with the test specimen fastened to the lever through a saddle arrangement close to the pivoted end. The load G is applied through another saddle arrangement at the opposite end, and the lever ratio is such that any applied load is multiplied 24 times at the test specimen. Knife edges are used at all points of bearing, and at some points, for example, at K, the knife edge is given a slight bevel so as to allow a certain amount of side adjustment.

The test specimen used has a diameter in its reduced section of 0.505 in. and an overall length of $5^1/_2$ in. Consequently the specimen is not of sufficient length to extend from the lever to the upper support but is screwed into adapters. As these adapters must themselves extend into the furnace, they were made from a highly alloyed heat-treated steel.

A rather wide range of loadings is possible with the set-up as shown, loads from 4000 to 80,000 lb. per sq. in. being easily

obtained. For loads below 4000 lb., a smaller lever is used, by means of which loads as low as 1000 lb. per sq. in. can be obtained.

Heating and Temperature-Control Apparatus

The specimen is heated with an electrical resistance furnace, *D*, Fig. 2. A sectional view of this furnace is shown in Fig. 3. The furnace is wound so that the temperature over the entire length of the test specimen is practically uniform. The temperature gradient over the 2-in. gage length should never be greater than 10 deg. fahr.

A clamp arrangement is attached to the top of the furnace which swings into slots in the rod into which the upper end of the test specimen is screwed. This allows the furnace to remain in the same relative position with respect to the test piece regardless of what amount of elongation occurs. Another slot is provided close to the bearing *K* so that the furnace may be raised and fastened above the test specimen.

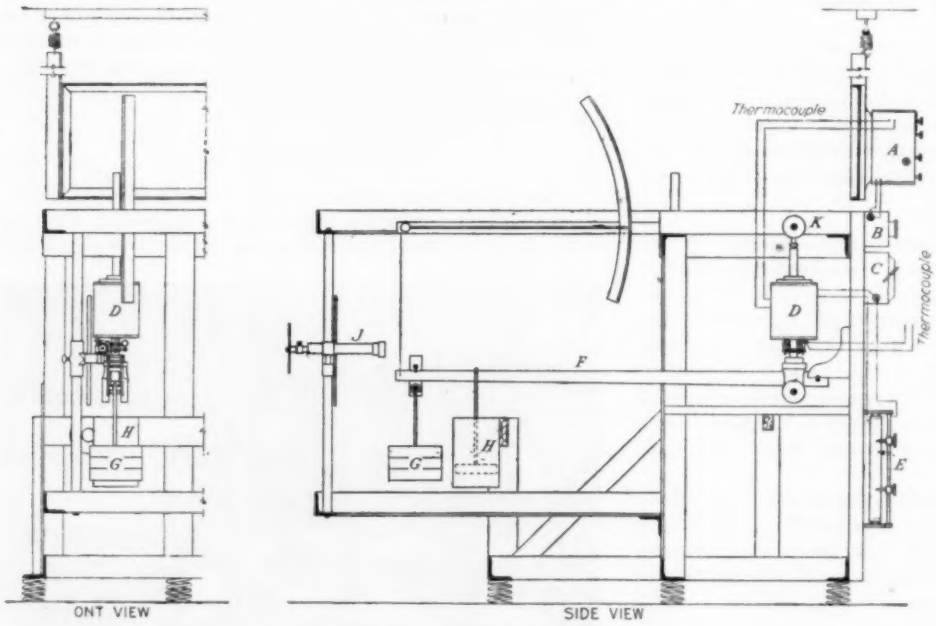

Fig. 2 Assembly of Flow-Test Apparatus

For maintaining the temperature constant, a separate Wilson Maeulen temperature controller is used for each individual furnace. The control thermocouple is placed close to the furnace winding, and a separate couple is fastened to the test piece itself. External resistances are placed in series with the furnace so that the current may be adjusted to a value just slightly above that required to maintain the furnace at the desired temperature. The automatic control throws off and on the full current.

The thermocouple for determining the actual temperatures of the test piece is wired to the outside of the specimen, care being taken to insure that the bead of the couple is pressed against the surface of the metal. These couples are connected to a ten-point Leeds and Northrup temperature recorder. Observations have shown the temperature at any given point not to vary by more than plus or minus 2 deg. cent.

Elongation-Measuring Device

An optical system is employed for determining any changes in length of the test specimen. A general view is shown in Figs. 1 and 2, while a detailed sketch is given in Fig. 3.

The apparatus consists of two parts. One part has for its function the transference of any motion of the test piece to some point outside the surrounding furnace, while the other measures any deformation that may occur.

A sketch of the mechanism employed for bringing any motion of the test piece outside the furnace is shown in Fig. 3. It consists of two collars, one of which is fastened to the upper gage marks on the test piece and the other to the lower ones. To each of these collars, rods are fastened which extend below the furnace. Rollers to which mirrors are attached are placed between the rods and held in place by friction produced by two springs drawing the rods together.

An elongation of the test piece will cause the lower collar and the inner rods to move downward with respect to the remaining rods. This movement will produce a rotation of the rollers, which in turn will rotate the mirrors fastened to these rollers.

On the first units constructed the rods were fastened to the upper and lower collars through the knife-edge arrangement shown in Fig. 3. Some difficulty was encountered in keeping the screws tight, and also in removing them at the end of the test. A slightly different arrangement is now being used which has yielded satisfactory results. This consists in replacing the knife seat with a projecting pin having a slight taper. The knife edge on the rod is replaced by a slightly tapered hole which fits over the projecting pin with their tapers in opposite direction. This amounts to replacing the knife edge with a "knife circle." The rod is held on to this pin by the same springs as hold the rollers in place.

The method used for recording the deformation is based upon the Gauss-Poggendorf principle of measuring angles by means of mirrors. There are two main methods that utilize the principle for measuring the elongation in the tensile test, namely, the Bauschinger and the Martens.

In the first, the mirrors are attached to cylindrical rollers which are turned when the specimen elongates, thereby transforming the linear motion of the rods coming from the above-described collars into rotation. In the Martens apparatus the elongation is transformed into rotation by inserting metal prisms of rhombic cross-section between the rods. As the specimen elongates the prisms will tip, rotating attached mirrors.

The angle of rotation is in both cases measured by observing through a telescope the movement of the images of a fixed scale in the mirror.

In both systems an adjustment of either the prisms or rollers is necessary after a certain amount of deformation has occurred. In the case of the Bauschinger method, this amount of measurable deformation is only limited by the range through which the scale can be observed; while with the Martens one must also take into consideration the danger of the prisms' turning over.

The measuring system employed in this creep apparatus is a modification of the Bauschinger which, in the opinion of the authors, has some advantages over the Martens arrangement. These may be listed as:

1 The edges of the prisms in the Martens apparatus will have some tendency to dig into the rods, especially during a long-time test, unless the edges of the prism are dull. In the first case the movement of the prisms will be impaired, while in the second, rotation would be produced and the exact diameter of the rotating part would be unknown.

2 A true cylindrical roller can be made more easily than a small prism of accurate dimensions. For the accuracy of measurements desired in this work a hardened steel would be suitable for the rollers, while with the prisms an extremely hard material, as stellite, is desirable.

3 The necessary readjustments that must be made in either

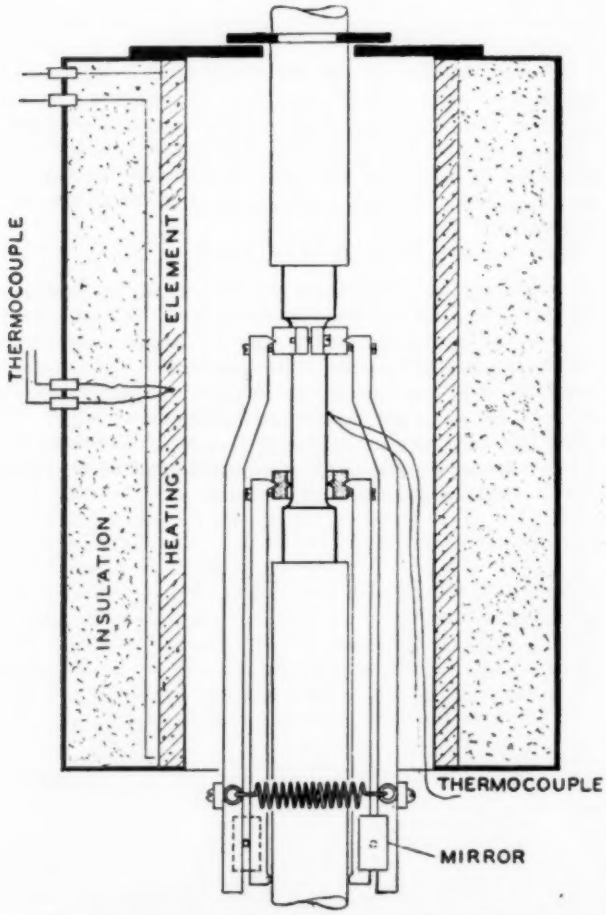

FIG. 3 FURNACE AND EXTENSOMETER USED IN FLOW TEST

system after a certain amount of deformation are more easily accomplished with the modified Bauschinger system than with the Martens. The ease of readjustment becomes of even more importance when it is considered that such changes must be made while the rods are heated, and that the apparatus must be disturbed as little as possible.

The actual amount of magnification that may be obtained with this type of system can be shown by considering the geometry of the system. In Fig. 4, R_1 and R_2 are the rods leading from the upper and lower collars, respectively. The solid and dotted circles are the positions of the roller before and after R_2 has been displaced downward. The lines AB and $A'B'$ are diagonals before and after rotation. The point B besides being rotated is translated a distance equal to the displacement of the center of the roller C. The sum of these two distances, the arc of the angle of reflection and the translation, constitutes the distance V. Considering only small angles, negligible error is made by assuming that a diagonal in the direction near to the perpendicular to the rods rotates as if the tangent of its angle is equal to V/d, where d is the diameter of the roller. Such a diagonal may be taken as a perpendicular to the surface of the mirror fastened to the roller, and therefore the mirror also rotates around an angle with tangent V/d.

If the angle at which the beam of light strikes the mirror is α, then the angle of the reflected beam would also be α. If the mirror be rotated through an angle β and it is required that the reflected beam have the same direction as before, namely, through the axis of the telescope, the incoming beam must suffer a change in direction of 2 $(\alpha + \beta)$. The angle of rotation of the mirror is thus doubled by reflection.

Now from simple geometry, it is seen that $V : d = s : l$. If

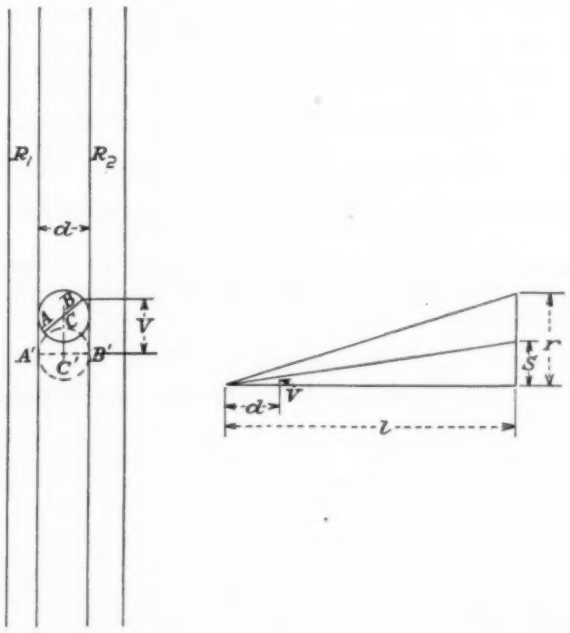

FIG. 4

only small angles are concerned, $s = {}^1/_2\, r$ without appreciable error. The equation thus becomes $V: d = r : 2l$, or $V = dr/2l$. .

In the set-up being considered the diameter of the rollers is 0.1 in. and the distance from the telescope to the face of the mirror 85.625 in. The ratio of V to r is therefore 0.1 : (2 × 85.625) or 1 : 1712.5.

The scale employed is graduated to half-millimeters. The readings are taken over a 2-in. gage length. On the assumption that readings can be accurately obtained to a quarter of a millimeter, the accuracy becomes 0.25 mm. on scale = 0.0000028 in. per inch on test piece.

PROCEDURE FOR OPERATION

After the extensometer apparatus has been assembled, the test specimen is brought to the desired temperature and maintained there for one day before the load is applied. Readings are taken immediately before and after the application of the load so the amount of elastic deformation may be obtained.

The temperature fluctuations, even though of the order of ± 2 deg. cent., are sufficient to cause a noticeable rotation of the mirrors. For this reason, when readings are being taken it is necessary to read a range on the scale rather than a definite

number. The reported reading is the mean value of the range.

The test at any given load is continued for a sufficient length of time to allow an accurate measurement of its rate of creep. It has generally been found that 400 hours is suitable. In some cases when the points fall almost exactly on a straight line, shorter periods of time may be used.

After the rate of creep for a given load is definitely known, then the load is either increased or decreased, depending on the amount of flow previously obtained. This process is repeated at least four times so as to give sufficient values to be plotted logarithmically.

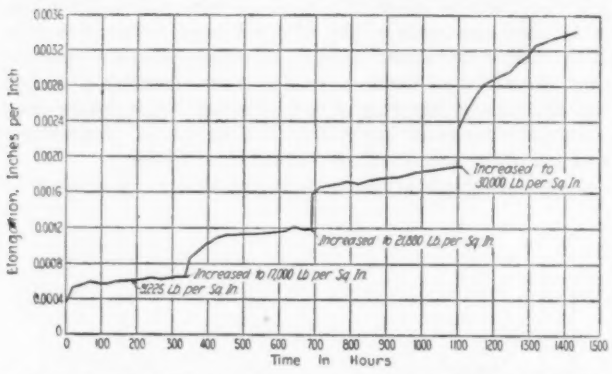

FIG. 5 CREEP TESTS ON SELECTED ALLOY STEEL AT 1000 DEG. FAHR. (538 DEG. CENT.)

(Chemical composition of "R" Steel: C, 0.02; Mn, 0.49; Si, 2.36; Cr, 18.00; W, 0.00; V, 0.01; Ni, 10.27.)

TYPICAL EXAMPLE OF RESULTS

As a typical example of the results which may be obtained with this apparatus, Fig. 5 is given. This particular alloy was tested at 1000 deg. fahr. and subjected to four different loads which ranged from 9225 lb. to 30,000 lb. per sq. in.

The smallest division on the elongation scale used represents a value of only one hundred-thousandth of an inch, yet in practically all cases the points fell on uniform curves.

It should be observed that in each case after the application of the load an appreciable time was required before the specimen began elongating at an approximately constant rate. For example, when the load was increased from 9225 lb. to 17,000 lb. per sq. in., over 100 hours were required for the rate of elongation to become constant. In some runs, even longer periods of time than this are required.

LIMITATIONS AND ADVANTAGES

The chief limitation to the use of this type of apparatus is that it must be practically free from all vibration. In our laboratories this has been accomplished by mounting the apparatus as a whole upon springs, by attaching dashpots, *H*, Fig. 2, to each lever, by suspending all control instruments free from the apparatus, and by using fine and flexible wires for all electrical connections.

The advantages may be listed as follows:

1 Readings of a high degree of sensitivity are obtainable
2 The readings are taken directly on the test piece itself, and are independent of any deformation which may occur in other parts of the apparatus
3 No side openings are necessary in the furnace which may affect the temperature distribution
4 The test piece itself is short enough so that conditions are more favorable for securing both uniformity of temperature and uniformity of metal.

Economics of Heat Transfer

By W. J. WOHLENBERG,[1] NEW HAVEN, CONN.

There is a set of proportions ideal for the operation of every manufacturing structure, the discovery of which is predicated upon ascertaining what may be called the economic units into which any structure may be divided. A statement of the cost of operation of an economic unit is here called the economic factor. Such factors assume, depending on their form, either maximum or minimum values for the ideal set of proportions. It is shown how an attack from this point of view may be employed in an attempt to evaluate ideal proportions for the heat-absorbing surface of a steam generator.

DISCUSSION of this subject will be begun by stating the following hypothesis: *There is a set of proportions which will prove most economical in operation for every engineering structure.*

The discovery of this particular set of proportions is predicated, first, on the ascertainment of what may be called the economic units into which any system or structure may be divided. The economic unit may, in this sense, be defined as any part of the system or structure within which a change of proportions will still leave the cost of operation for the other parts of the structure or system the same. A general statement of the cost of operating an economic unit may be set up in mathematical form, and such a statement is here called an economic factor. The unit should be so proportioned that such an economic factor assumes a minimum value. In another case the economic factor may express the amount of saving that is possible by a change in one or more dimensions of the structure. Then the value of the economic factor is obviously a maximum when it represents the most economical conditions.

For a steam-generating plant the economic unit is, in the last analysis, the steam plant; but it may be taken as a reasonable procedure when investigating the most economical extent of the heat-absorbing surface, to consider the extension of this surface as continuing from any point in the convection zone.

The economic factor may then be set up as follows:

$$I = \frac{R}{2000}\sum NL_s - \left[\frac{R}{2000}\sum Nq + X_s x_s + X_s x_s + X_c x_c\right] \quad \ldots\ldots [1]$$

in which

R = cost of burning fuel, say coal, dollars per ton
L_s = fuel saving effected by additional heat-absorbing surface, expressed as lb. of fuel per hr.
N = hours per year of operation at each load
q = extra fuel, lb. per hr., chargeable to auxiliary because of extension of surface
$X_s x_s$ = additional fixed charges plus maintenance on extra draft-producing equipment necessary for extra surface
$X_c x_c$ = additional fixed charges plus maintenance on extra additional building that may be required by the additional surface
$X_s x_s$ = fixed charges plus maintenance on extra surface in place.

In this equation I now represents the net saving in dollars per year because of the extra heat-absorbing surface. It is to be noted that, as the economic factor stands, no charges are made for extra labor or extra fuel costs due to stand-by losses. It is thus assumed for this case that extra labor and fuel stand-by costs are the same whether or not the extra heat-absorbing surface is present.

The most economical proportions of the steam generator under consideration are thus those which will yield a maximum value for the foregoing statement of the economic factor. Should even a small addition to the convection zone yield a negative value to this factor, it shows that the boiler convection zone is

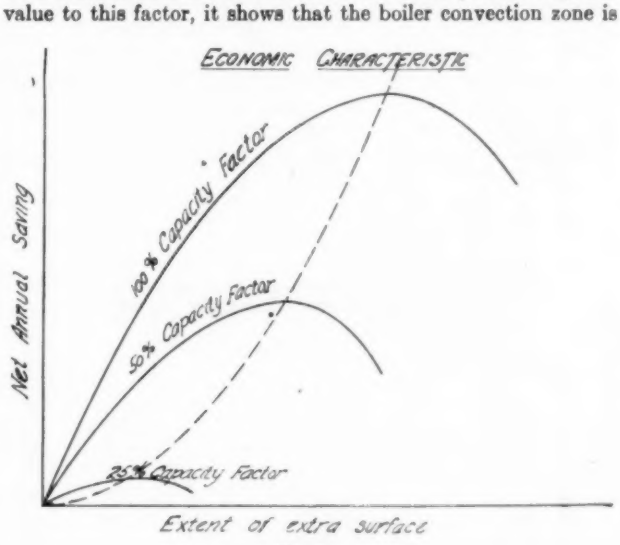

FIG. 1

already too large to be justified. A solution for values of the economic factor as the convection zone is extended in length—for instance, by economizer or air-preheater surface—will yield a set of curves of which those shown in Fig. 1 are typical, if the relation between first cost of the surface and its extent may be represented by a smooth continuous curve. This would be the case, for instance, if the cost per unit of surface were a constant regardless of its extent or if the change in cost per unit surface varied continuously and without any sharp breaks as the surface was extended.

The abscissa in Fig. 1 represents the extent of the additional surface, and the ordinate represents the dollars saved per year. If the unit is in operation all of the time, the capacity factor is 100 per cent, and the hours of operation per year N is equal to 8760. This is the condition under which the fixed charges have the least influence in determining where the surface should cease and the hourly fuel saving has the greatest influence. Therefore a larger extent of the surface is justifiable than for the lower capacity factors of 50 and 25 per cent.

The peaks of the curves shown in Fig. 1 may be used to plot a second curve shown in Fig. 2, in which the best surface is directly related to the capacity factor.

Whether or not such savings over the straight boiler operation will be realized depends upon how accurately the average capacity factor and the fuel cost over a period of time may be estimated. This is often very difficult, but in any case an analysis of this kind yields information by means of which guessing may be

---

Lecture delivered at the S.P.E.E. Summer School for Teachers of Mechanical Engineering, held at Purdue University, Lafayette, Ind., June 27 to July 18, 1929.

based on a better foundation. It will at least show whether any worth-while savings are possible.

General Solution of the Problem

Inspection of the expression for the economic factor I shows

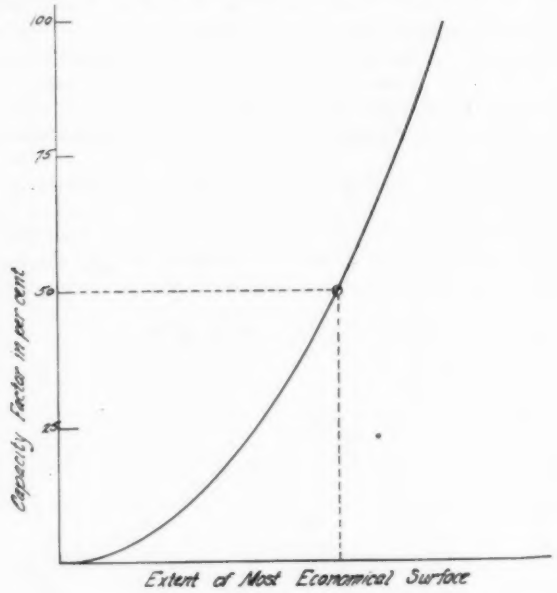

Fig. 2

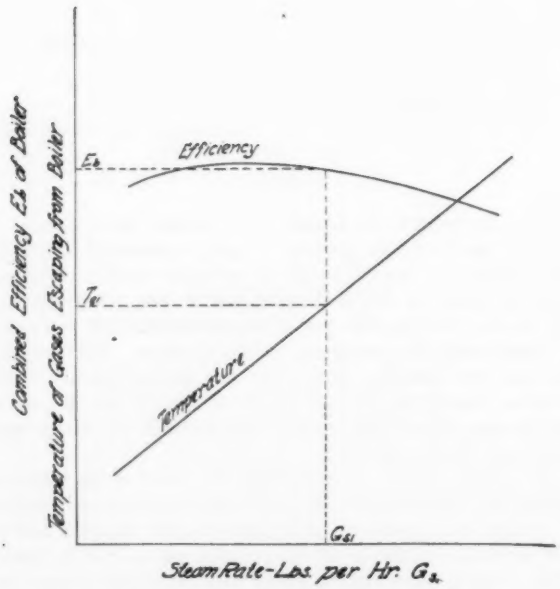

Fig. 3 Performance Characteristics of Boiler

that the only terms in it which relates directly to the performance as changed by the additional equipment are:

L_s = the fuel saved by the additional surface, and
q = the extra fuel requirement by auxiliaries.

These factors must thus be evaluated before any values can be worked out for the factor I. The problem thus divides itself into two parts. The first part is concerned with the influence on energy distribution and energy losses of the extension of the surface. The information yielded, from the energy point of view, is established once and for all time if the physical proportions of the unit are unchanged and if the data on which the computations have been made are reliable. It is in the second part of the solution that such factors as the fuel cost R, the hours of operation N, and the costs X and x are introduced. Such quantities may change from time to time and are subject to outside influences, and values adopted for them in arriving at the best proportions of the equipment must be chosen only after weighing each item very carefully.

Solution for the Energy Distribution

In beginning this phase of the solution of the problem let us assume that both the total output, pounds per hour per steam generator, and the fuel have been determined. Also that the combustion arrangements have been fixed so that it is possible to

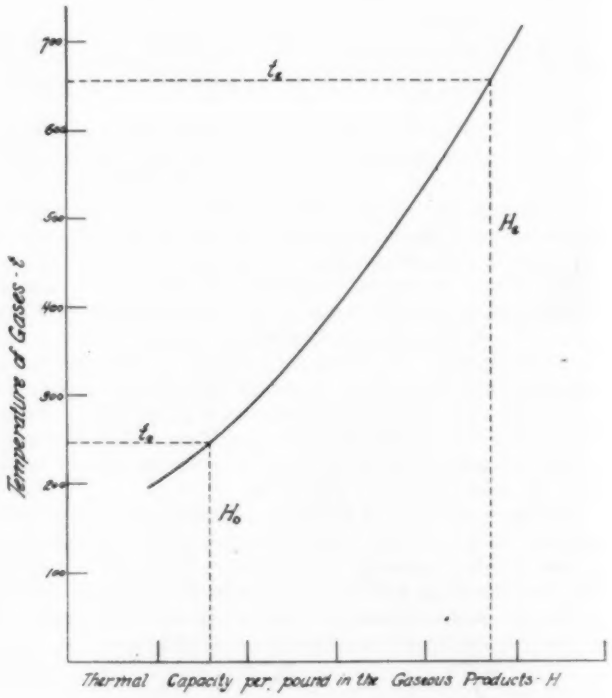

Fig. 4 Thermal-Capacity Curve

predict the amount of air that will be required for combustion for each pound of fuel that is burned.

The steam-generating unit will consist of the combustion apparatus and the boiler, plus such additional heating surface in the form, say, of economizer surface as it is found economical to install. It is the influence of the extent of this additional surface which it is proposed to investigate.

The available data on operation include a curve, Fig. 3, furnished by the manufacturer, showing the relation between the temperature of the gases escaping from the boiler and the steam output for the combustion conditions as they may exist when burning the fuel under consideration. A second curve on the same figure shows the relation of the combined boiler efficiency to the steam output, and thus determines the fuel cost if the unit is operated without any extension of the heat-absorbing surface.

The additional surface will reduce the energy loss in the escaping gases by reducing the temperature of these gases. This reduction in loss may be represented as a fuel saving, whose magnitude for a given rate of steam production depends on the hours

per year at which this unit is operated at the specified rate or rates.

The energy as heat that is saved by the extra surface is of course fixed by the reduced thermal capacity of the gases as they escape at the lower temperatures, and the amount of the extra surface that is required depends upon the mean temperature differences between the gases and the surface and on the velocity of the gases as they sweep over the given arrangements of these surfaces. Such a curve as is shown in Fig. 4 is thus necessary for accurate evaluation of both the reduction in thermal loss and the surface required. It is a segment of the curve showing the relation between the thermal capacities per pound of the gaseous product and the temperatures of the gases.

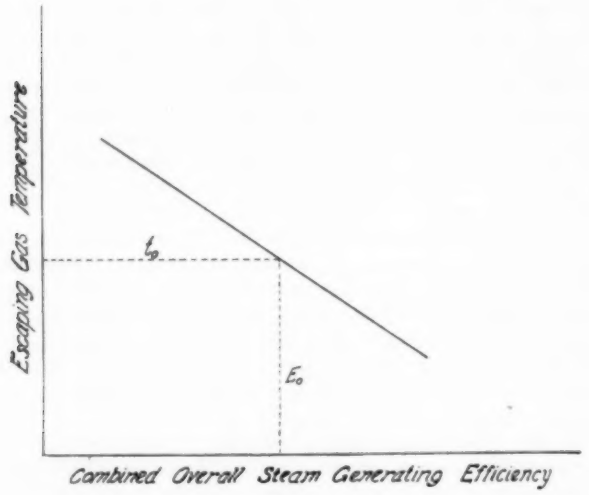

FIG. 5

It represents the temperature path along which the gases are cooled.

Another curve shown in Fig. 5 shows the relation between the overall steam-generator efficiency E_o and the final escaping-gas temperature t_o. Values for its determination are derived from heat balances, in which may be included for each of a number of final temperatures the following losses:

1 Loss due to incomplete combustion
2 Loss due to radiation and unaccounted for
3 Loss due to energy carried out in final escaping gases.

The magnitude of the third of these losses may be taken directly from the thermal-capacity curve shown in Fig. 4, when the gaseous weight P per pound of fuel is known.

With this information the curve shown in Fig. 6 may be found. Here the final escaping-gas temperature t_o is related to the gas weight g in pounds per pound of steam generated. A point on the curve may be found for any temperature t_o by determining first the pounds of fuel that will be required to generate a pound of steam. Thus

$$G = \frac{(i_1 - i_f')}{E_o \cdot V} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

in which $(i_1 - i_f')$ represents the heat added per pound of steam E_o, the overall efficiency at temperature t_o, V the calorific value of the fuel, and G the pounds of fuel per pound of steam. The gas weight in pounds per pound of steam then follows from the relation

$$P \cdot G = g \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

in which, as before, P represents the total gas weight per pound of fuel.

The relations shown by the curves in Figs. 4, 5, and 6 are obviously determined independently of the equipment involved. They set up for the assumed combustion conditions and final escaping-gas temperatures what the energy relations must be. The equipment will now have to be proportioned to meet such of these conditions as we choose to fit into the picture.

Temperature of Gases Escaping From the Boiler When the Economizer Is in Place

For given conditions as to steam generation, initial feedwater temperature, and final steam heat content, the temperature of the gases escaping from the *boiler* proper is lower when the economizer surface is in place than it would be should no such extra surface be installed. This reduction in temperature at this point is due to that reduction in gas weight when the extra surface is in place which results from the reduced fuel consumption. This in turn reduces the gas temperature at any section of the gas stream if the combustion conditions remain constant.

Now in order to find out how much surface should be installed in the economizer it is obviously necessary to know what the temperature of the gases entering the economizer is, when it

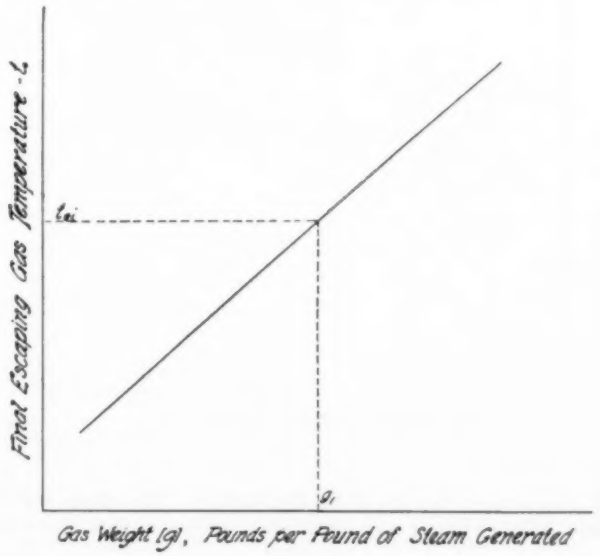

FIG. 6

(the economizer) is in place beyond the convection zone of the boiler. It is therefore necessary to relate the temperature t_e of the gases escaping from the boiler to the gas weight flowing through the boiler when the boiler-surface temperatures are substantially as they would be with the economizer in place.

Fortunately, with the data at hand this is a rather simple problem, because the boiler-surface temperatures are fixed by the saturated-steam temperatures going with the pressure which exists. This is not altered when additional heat-absorbing surface is installed beyond the so-called boiler proper. We now use the data furnished from the manufacturer's curve, Fig. 3, together with that shown in Fig. 6 to compute values for a new curve relating the gas weight flowing through the boiler to the temperature of the gases escaping from the boiler, which is the temperature at which they enter the economizer. Thus, for a given steam-generation rate, G_{s1} pounds per hour, the gas temperature from Fig. 3 is shown to be equal to t_{e1}. From Fig. 6 we find that at the temperature t_{e1} the gas weight per pound of

steam is g_1. The total gas weight, pounds per hour, for the temperature t_{e1} escaping the boiler is thus

$$g_1 \times G_{s1} = G_b$$

By computing a number of such points the curve of Fig. 7 is established.

The only error that is introduced in this computation results from the fact that the superheater, if one is in place, will absorb less heat with the economizer in place than it does if the boiler alone is absorbing the energy. The same quantity of steam is of course flowing through the superheater in either case, but less gas weight is flowing over the superheater in the first case than in the second. This may make it necessary to use a slightly larger superheating area under the second as compared to the first condition, but the error introduced in the total gas-temperature curve is from this cause only a very small one.

Energy Relations in the Economizer

With the foregoing information it is now possible to determine for any final escaping-gas temperature t_e the temperature t_s

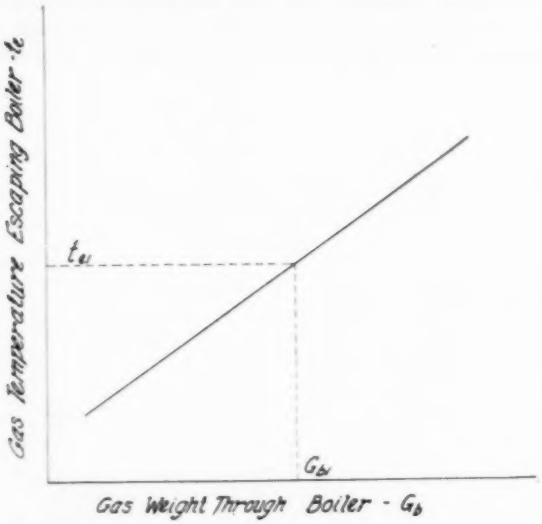

Fig. 7

of the gases entering the economizer surface. The energy which must be absorbed at the economizer surface is then equal to

$$G_s \cdot G \cdot P\,(H_s - H_o) \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

in which the thermal capacities $(H_s - H_o)$ are taken from the curve of Fig. 4 corresponding to the temperatures t_s and t_o. The fuel weight G is determined from Equation [2], i.e.,

$$G = \frac{(i_1 - i_f')}{E_o \cdot V}$$

in which the overall efficiency E_o may be taken from the curve shown in Fig. 5.

But the energy shown by [4] must be absorbed in the feedwater, whence

$$G_s \cdot G \cdot P \cdot (H_s - H_o) = G_s(\Theta_s - \Theta_o) \ldots\ldots\ldots [5]$$

in which Θ_o and Θ_s represent respectively the temperature of the feedwater entering and of that leaving the economizer surface. This equation is solved for the temperature Θ_s of the water escaping from the economizer.

There are now available, with one important exception, sufficient data to solve for the surface requirements in the economizer. Thus the total energy to be absorbed is represented by the relation

$$G_s \cdot G \cdot P(H_s - H_o)$$

and the temperature differences at the two ends of the economizer surface are

$$(t_s - \Theta_s) \text{ and } (t_o - \Theta_o)$$

The important exception is the remaining data which are necessary to establish what the unit rate of heat transfer may be for this surface.

Mode of Heat Transfer in the Convection Zone

The transfer of energy from gases to a surface across which they are flowing is in reality a very involved process. The final stage of the transfer is conduction through a thin surface film of gas which adheres to the metal surface. If any element of the metallic surface is to receive considerable energy by this process, the gases containing the energy as heat must be washed up to it at a high rate. This washing or scrubbing action is important also in reducing the thickness of the conducting gaseous film, which offers the principal resistance to the flow of energy into the metallic surface.

It is not only the general state of the motion of the gases, but also the smallest details of this motion, such as turbulence, which play an important part in the rate at which the energy transfer takes place. The density of the fluid, its viscosity, and also its thermal capacity enter into the problem. Finally, for the higher temperatures the chemical composition of the gas may have to be considered because certain constituents radiate energy as heat.

At the usual temperatures which exist in the lower part of the convection zone of a steam generator the radiational transfer is not a considerable factor. The temperatures are low here, and for close tube spacings the individual gas streams have small mean diameters, so that the thickness concentration functions of the radiating constituents of the gases have but small values. For such cases at least, then, the variables may be reduced to the ordinary variety aforementioned.

Boussinesq was the first to derive a complete rational equation based on the dimensional reasoning for the so-called coefficient of heat transfer. His equation involved the tube diameter, the velocity of the fluid, its density, its conductivity, its viscosity, and its specific heat or thermal capacity. It was developed for gases flowing through tubes, and may be applied with confidence only to rather simple cases when the conditions are within the limits for which the constants were determined. It assumes uniform thickness of the final conducting film, and so may not be applied in its original form to the case of gases flowing transversely across the outside of tubes and through which water or steam is flowing. The latter is the usual arrangement for the larger steam generator.

In a paper presented before The American Society of Mechanical Engineers in 1926, Chappell and McAdams include the derivation of a formula which, as an example, it is proposed for use in such cases. In their development they begin with the work of Boussinesq and submit this, together with some of the later developments, to a critical review. The final formula for staggered tubes is stated as follows:

$$h = \frac{0.8\sqrt[3]{T_f}\,V^{(0.60\,+\,0.08\,\log\,D)}}{D^{0.53}}\left(1 + \frac{D}{W}\right) \ldots\ldots [6]$$

in which

h = coefficient of heat transfer B.t.u. per sq. ft. per degree per hr.

T_f = arithmetical mean temperature of gas stream and tubes, deg. fahr. abs.
V = mass velocity of gas, lb. per sec. per sq. ft. of free area of cross-section
D = outside diameter of pipe in inches
W = distance in inches between center lines of adjacent pipes in a row taken at right angles to air flow.

The last term of this equation is a correction factor which is applied when more than a single tube is involved and when, furthermore, the tubes are in a staggered arrangement. In using such a formula it should be kept in mind that the constants in it have been determined for certain specific arrangements, sizes of tubes, and velocities. If in another case there is a wide divergence from these conditions, they may not fit. It is thus always better to have a few check points, at least, for such arrangements and conditions as are under consideration. The formula then serves as a basis for establishing the relativity of one condition with respect to another, and the whole scene is shifted and anchored to such values of the constants as will suit the few points of reliable information which may be at hand concerning the particular type of arrangement under consideration.

Selecting the Surface Arrangement

Assuming that either from sufficient direct experimental evidence there is sufficient information for determination of the values of the coefficient of heat transfer and their variations or that suitable constants have been established for such a formula as [6], the solution of the problem may be continued. At this point it will be necessary to assume either the surface arrangement and its proportions or the gas-flow conditions. In the first case the resulting gas flow will have to be determined usually by trial and error, and in the second case the flow areas must be so proportioned that the assumed conditions of flow result. This is usually the more simple form of procedure.

By means of it a number of different cases may be investigated to show, for instance, the influence of gas velocity on the economic proportioning of the surface. For a given set of conditions otherwise, there would then result one economic characteristic for each of the assumed gas-flow rates.

Having determined the flow conditions and hence the coefficient of heat transfer, the extent of the surface is determined for any given final temperature by the usual procedure. The mean-temperature difference is computed as before outlined by reference to the gas and water temperatures at the boiler and economizer ends, respectively. The surface is then made just large enough so that it will absorb the energy which must be transferred from the gases in order to reduce their temperature from that of the boiler exit to that assumed for the economizer exit. The solution is carried through for a number of final temperatures t_e.

Fuel for Extra Draft Requirement

In some instances the increase in draft loss through the system may provide the limiting conditions. If it were not for the rapidly increasing resistance to the flow produced by increasing the gas velocities, it would be desirable, as has been shown, to greatly increase these in order to increase the rate of heat transfer. Indeed, for a given rate of gas flow in pounds per hour over a given amount of surface, the higher the mean gas velocity the lower the final escaping-gas temperature and hence losses. From this point of view by itself, it would thus be desirable to increase the gas velocities above present practice, up to such magnitudes that the resulting increased heat-transfer rate would attain such levels as to cause the resulting rise in temperature of the metal itself to become the condition limiting the gas velocities.

The resistance to flow, however, increases very rapidly as the velocities become higher and higher, and long before the above limiting surface temperatures are reached the required extra power expenditure for draft loss is prohibitive.

The resistance to flow or draft loss may be set up in an approximate mathematical form as follows:

$$h = h_o \left(\frac{G}{G_o}\right)^2 \cdot \frac{T}{T_o} \cdot \frac{N}{N_o} \quad [7]$$

In this formula G_o, T_o, and N_o represent, respectively, rate of gas flow (lb. per sq. ft. flow area per hr.), mean absolute temperature of the gases, and length of the flow path as measured in any convenient units for a draft loss of h_o inches of water. The length of the flow path may be expressed, for example, as the number of tubes deep in the direction of the gas flow, or as

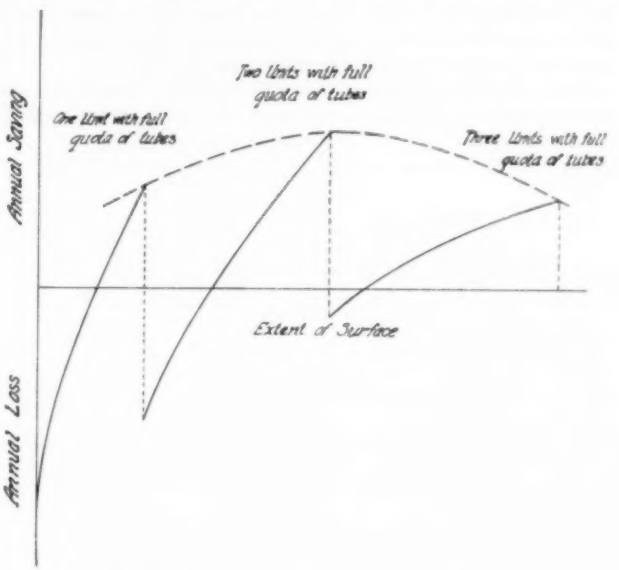

Fig. 8 Economic Characteristic

the length of the tubes in case the flow is parallel to the tubes.

For any other set of flow conditions, then, with substantially the same type of tube arrangement and tube size the draft loss is h inches of water when the gas-flow rate is G lb., the mean absolute temperature T degrees, and the flow path is, say, N tubes deep.

The extra power requirements for draft may thus be computed after having determined the extra draft loss. The extra fuel requirements for this additional power will then depend upon other conditions in the plant such as the existing heat balance, i.e., whether or not the exhaust steam from auxiliary units may all be condensed for feed heating, or whether an electric motor is used for driving the fan and which is supplied from a house generator or indirectly from the main generators.

This now concludes the discussion of the problem as to methods of evaluating the various quantities of energy that are involved. That which remains is concerned with the substitution of values in the equation representing the economic factor.

Setting Up the Economic Factor

At this stage of the solution the following information is available for the given rate of steam generation with the given conditions of combustion: The temperature t_b of the gases escaping from the boiler when no economizer surface is in place. The temperature t_e of the gases escaping from the economizer

when the unit consists of the boiler plus the economizer. The combined efficiencies of operation in the two cases may now be obtained from the temperature efficiency characteristic of Fig. 5. Let the efficiency for the temperature t_b be E_b and that for t_e be E_e. The fuel saving, L_s lb. per hour, because of the extra surface is now

$$L_s = \frac{Q}{V}\left(\frac{1}{E_b} - \frac{1}{E_e}\right)$$

in which

Q = heat absorbed by the water and steam in B.t.u. per hour, and

V = calorific value of the fuel.

It should be noted that the credited heat saving is not exactly equal to the heat absorbed by the economizer surface, because, when this is in place, the boiler proper, by virtue of the reduced gas flow, absorbs a little less energy than it does when this is not there. The economizer thus absorbs a little more energy than is represented by the actual heat saving due to it.

The only other factor in Equation [1] which merits any discussion now is perhaps the first cost X_s of the extra surface. How this varies with the extent of this surface is of course determined by the variation of the cost per unit of surface with its extent. In some special cases the cost per unit of surface may remain constant or vary in a continuous manner with the extent of this surface, but usually this is not so. Let us consider for a moment an economizer which is made up of units comprising upper and lower drums connected by the surface in the form of tubes. The principal cost of such a structure is in the drums. The first square foot of tube surface would then have to be charged with the cost of the tubes plus the drums, and for small amounts of tube surface in conjunction with each pair of drums the cost per unit of effective surface would be exceedingly high. As the number of tubes between any set of drums is increased, the unit cost is reduced, and finally with the full quota of tubes in place it has been reduced to a reasonable value. An economic characteristic developed on the same basis as that shown in Fig. 1 may, for such cases, appear as shown in Fig. 8.

It is obvious that for such conditions the real unit of heat-absorbing surface may be a set of drums with its full quota of tubes, and the problem resolves itself into the question of how many such units should be installed.

Effect of Air and Turbulence on Condenser-Tube Deterioration

Progress Report No. 3 of the A.S.M.E. Special Research Committee on Condenser Tubes,[1] Comprising the 1929 Report of Its Sub-Committee on Questionnaire[2]

DURING the past year the Sub-Committee has been engaged in an intensive study to devise means of determining the quantities of air and the degree of turbulence within the condenser water boxes and tubes, and correlating the results with tube deterioration. The work so far has been carried out in the Hudson Avenue and the Gold Street stations of the Brooklyn Edison Company, supplemented by laboratory experiments at Hudson Avenue. The methods used are illustrated in the diagrams and photographs included in this report.

The field work consisted of obtaining samples at the points illustrated in Fig. 1 at various points in the circulating-water cycle. Complete data are tabulated and show a decided increase in the volume of air from the inlet tunnel to the condenser discharge due to the release of the air with drop in pressure.

In order to visualize the free-air content, glass tubes were attached to the condenser heads as shown in Figs. 2 and 3. In Fig. 2 the samples were taken from the inlet water box of the condenser and discharged into the outlet water box. These tubes were attached at right angles to the face of the condenser head in prolongation of the actual condenser tubes. A continuous stream of small bubbles was noted with intermittent flow of large bubbles which broke up into a large spiral of smaller bubbles. The vertical glasses were installed both at Hudson Avenue and Gold Street on two different types of condensers. One was a single pass at Hudson Avenue and the other a two pass at Gold Street. The results were about the same and are illustrated in Fig. 3. The water level at the top of the pass surged up and down in 10- to 15-sec. cycles for a distance of from 12 to 18 in., thus indicating that the upper tubes were entirely empty at times and then filled with water. Figs. 4 and 5 show the tube-failure records for two condensers. It will be noted that the failures are coincident with the tubes which are subject to this intermittent flow of air and water, thus verifying the findings of a year ago that turbulence and entrained air are one of the principal causes of tube failure.

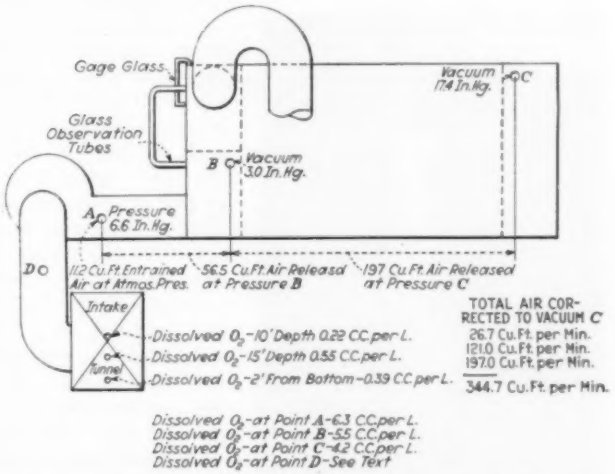

FIG. 1 DIAGRAMMATIC SKETCH OF INVESTIGATION OF AIR QUANTITIES IN CONDENSER

In carrying out the various experiments in the field some rather peculiar conditions were found which have not been fully solved as yet, the principal one being an apparent infiltration of air through the circulating-pump glands which on checking were tight and properly sealed when in operation. To attempt to solve this problem a laboratory set up was made as shown in Fig. 6. It consists of a paddle in a bottle driven by a shaft through a tightly fitting cork. The shaft was rotated with the bottle completely filled with water. Air bubbles gradually seeped through the cork along the shaft and down the impeller. The immediate conclusion appears to be that no matter how tightly sealed a shaft may be mechanically a film of air will work through under operating conditions unless an additional seal such as a water seal is provided. This is further borne out in the field, because when a circulating pump is shut down, the water in the condenser and pump will remain from 3 to 5 hr. before the vacuum is broken sufficiently to release the suction. The other source of entrained air which is under investigation is

A sample taken at the pump discharge at atmospheric pressure shows 16 cc. entrained air in 19 liters, equivalent to 11.2 cu. ft. of free air per minute.
The quantity of circulating water at low speed = 70,000 g.p.m., while at high speed this is increased to 100,000 g.p.m.
The pH value of the circulating water is 7.5 (slightly alkaline).

the possibility of a vortex in the suction leg. In order to determine the effect of such a vortex, samples were taken on the suction leg during operation of the pump and then periodically after the pump was shut down so that any air in the center of the suction leg would have an opportunity to diffuse. Samples obtained at point *D*, Fig. 1, with the pump operating indicated 0.10 cu. cm. of dissolved oxygen per liter. Twenty minutes after the pump was shut down the dissolved oxygen at the same point was 1.5 cu. cm. per liter and after 30 min. this had increased to 1.8 cu. cm. per liter. The increasing amount of air near the side of the pipe after the shut down of the pump would indicate that air was being sucked through the center of the column of water, and that in passing through the impeller this air is more thoroughly mixed with the water, thus accounting for the higher air content after passing through the pump, rather than because of gland leakage.

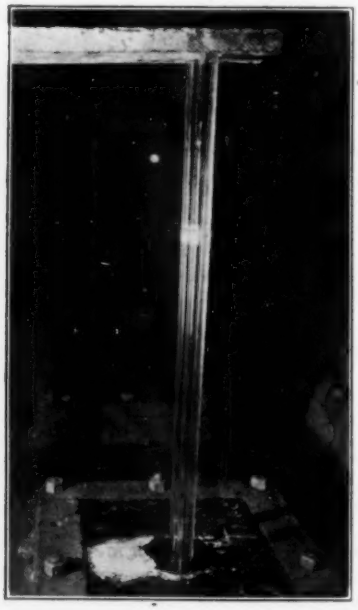

FIG. 2 GLASS TUBE ATTACHED TO NO. 3 CONDENSER AT HUDSON AVENUE STATION

In the laboratory, samples of circulating water were placed in a bottle, subjected to various degrees of vacuum, and the release of entrained air noted. This set-up is shown in Fig. 7.

Table 1 shows a maximum of 344.7 cu. ft. per min. of entrained air entering the second pass, which corresponds to 2.57 per cent of the total flow.

From the foregoing summary of the work already done it is evident that the results warrant a further study.

PLAN FOR FURTHER WORK

In a further study of condenser-tube deterioration the sources of information should be selected carefully. A list of approximately 12 operating companies and all the larger condenser and tube manufacturing companies should be obtained and their cooperation secured, preferably by personal contact, in an intensive study of the situation under the control of the sub-committee.

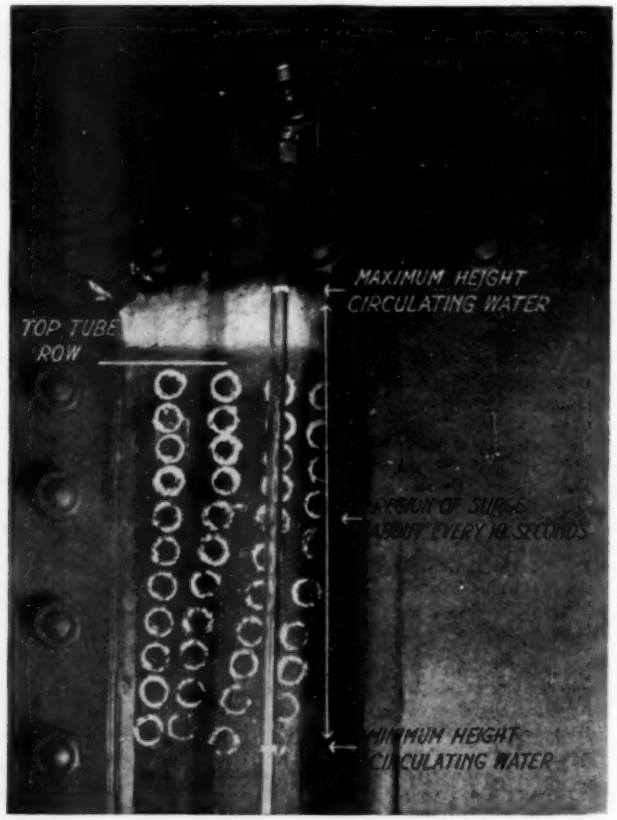

FIG. 3 GLASS TUBE ATTACHED TO NO. 5 CONDENSER AT HUDSON AVENUE STATION

Printed forms for data, sample attached, should be prepared periodically, and the operating companies requested to fill these in and send them to the sub-committee chairman. Periodic field inspection should be made by one of the sub-committee

members. An outline of the work to be covered is as follows:

1 *a* The quantity of air entering with and released from the circulating water at various points within the condenser and piping should be determined
   b How this air gets into the condenser should be established
   c Methods should be devised to reduce the quantity of free and released air
   d The effect upon tube deterioration should be noted by varying the quantity of air.
2 *a* The turbulence within the water-boxes and tubes should be studied
   b Means should be devised to reduce this turbulence
   c The effect upon tube deterioration should be noted by varying the degree of turbulence
   d The extent of the water level fluctuation in the upper rows of tubes and the length of time these contain no water should be determined
3 The pH value of the circulating water should be determined.

Suggested methods of obtaining information are as follows: The quantity of free air entering with the circulating water may be obtained by permitting a sample bottle of known volume to

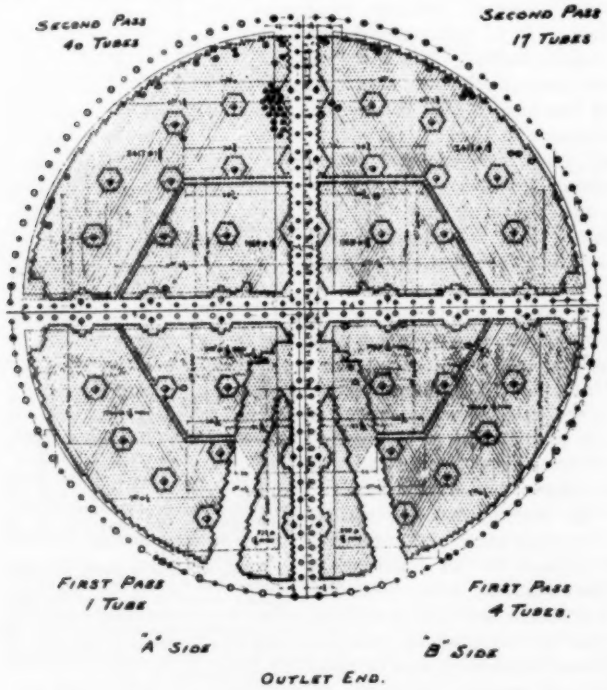

FIG. 4 TUBE-FAILURE RECORD FOR CONDENSER NO. 1

overflow for several minutes from a tap at the pump discharge and then rapidly corking the sample bottle. By permitting the sample to rest for a short period the free air will rise to the surface of the water in the bottle and measurement will then determine the proportion of air and water.

To obtain the quantities of air released from the circulating water in passing through the condenser it will be necessary to use an indirect method—i.e., determination of the oxygen content of the water in various parts of the system, and then calculating the corresponding quantities of air on the basis of 21 per cent O_2 and 79 per cent N_2 corrected for the existing pressures.

Samples for the determination of the O_2 content must be taken at the pressure existing at the point under consideration, and this will require a special sampling device. Fig. 8 shows such a device and indicates its method of operation.

The installations upon which these experiments are to be carried out should represent the best and worst conditions in a single plant in so far as tube deterioration is concerned. To expedite the work the installation selected should have complete records on tube failures in order that the present rate of tube failure may be established. If the records do not disclose the preceding rate of failure the condenser should be retubed and its rate of tube failure determined.

Having established the rate of failure and noted the quantities of released air, some method of reducing the quantity of released air flowing through the tubes should be instituted.

In order to accomplish this there have been several methods developed. One is to connect an air off-take from the top of the

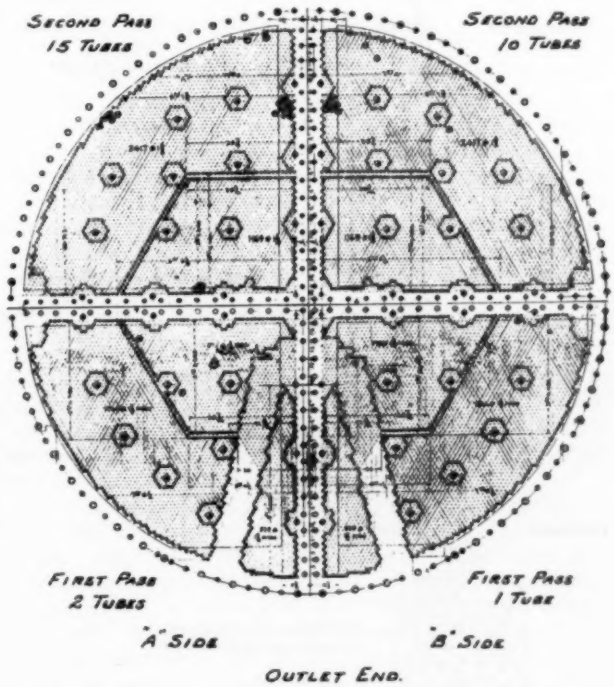

FIG. 5 TUBE-FAILURE RECORD FOR CONDENSER NO. 3

inlet waterboxes to the tail pipe. This method by-passes a large proportion of the released air. Another is to prevent the release of air in such way that it can concentrate in the upper tubes, by making the waterboxes shallow vertically; thus having a series of inlet boxes fed by separate inlets from the pump. Another proposed method is to proportion the inlet box to the flow.

On a small installation it might be feasible to put in a large enough pump to keep the circulating water under pressure throughout the condenser. The vacuum in the tail pipe may be broken by venting this to the atmosphere or a suitable baffle or damper arrangement could be placed in the entrance of the discharge piping thus restricting the flow and increasing the pressure within the condenser.

After these changes have been made the quantities of air (both free and released) should again be determined and a new rate of tube failure established and compared with the original.

STUDIES OF TURBULENCE WITHIN THE WATER BOXES AND TUBES

A study of turbulence is extremely difficult owing to the inability to visualize the action of the water as it passes through the water boxes and tubes.

No definite conclusions can be drawn unless some method is devised for observing the flow of the circulating water. A more or less elaborate set-up of instruments could be used to determine

the pressures, the velocities, and the direction of these velocities. The reliability of the results, however, would be doubtful inasmuch as the obstruction to free flow imposed by the instruments themselves may have a marked effect upon the characteristics that normally obtain.

Some suggestions for obtaining observed data are:

1 An operating condenser fitted with ample glass observation windows and illumination.

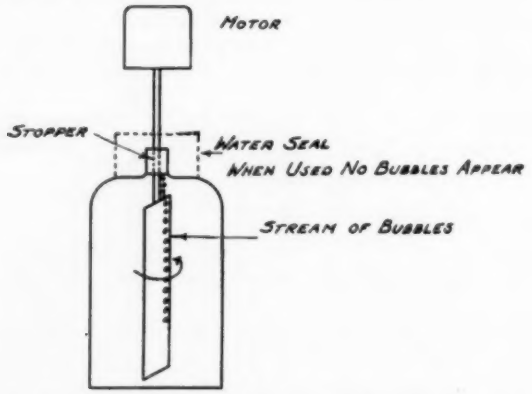

Fig. 6 Apparatus Used to Determine Infiltration of Air

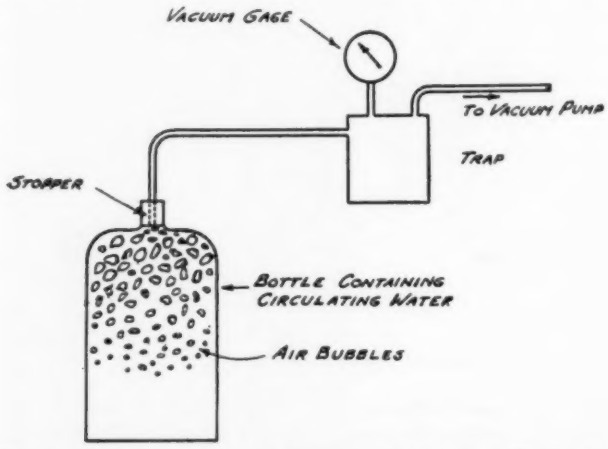

Fig. 7 Apparatus Used to Subject Circulating Water to Various Degrees of Vacuum and to Note the Release of Entrained Air

2 A variable tap and return arrangement utilizing a glass tube.

The operation in an experimental condenser fitted with liberal window space would approximate operation in an actual installation and would serve as a guide for comparison. By simulating water-box conditions as observed by several different applications of suggestion 1, the resulting tube flow could be noted, or by simulating observations as per suggestion 2, the corresponding water-box conditions should compare.

Also the effect of changes in tube entrance and water-box design could be observed readily, and any such experiments should first be tried in a condenser fitted with window installation. In designing this condenser provision should be made for varying the volume of the water boxes and their shape. It is suggested that the manufacturers of condensers and tubes be induced to build such an installation for the use of the sub-committee.

A tap and return arrangement could be used on an operating installation and an idea of the character of the flow within the tubes noted, and the movements of the air bubbles within the tubes observed. Such an arrangement should be tapped into the water-box head and returned to a point at different pressure. By tapping into the water-box head the direction of flow will be directly opposite that obtaining in the actual tubes within the condenser. This, however, cannot be avoided and will produce more accurate results than by tapping into the side of the water box, thereby causing an additional 90 deg. bend in the flow from water box to tube. This additional bend would materially affect the character of flow at the entrance to and within the tubes.

The condition of water flow within the water boxes and at the tube entrance can be noted best by observation, and the degree of this will depend upon the strength of the illumination and the clarity of the circulating water. The depth of vision when using an ordinary white light even of high candlepower is quite limited. It is therefore necessary to devise some form of illumination that will permit observation through the depth of the water box and so arranged as to cause practically no change in the flow within the water box. It is possible that a light other than white may produce the desired results. The installation of mercury or neon gas tubes may accomplish this. Experiments along these lines should be tried. The hydrogen-ion concentration of the circulating water may best be determined by the use of a hydrogen-ion comparator.

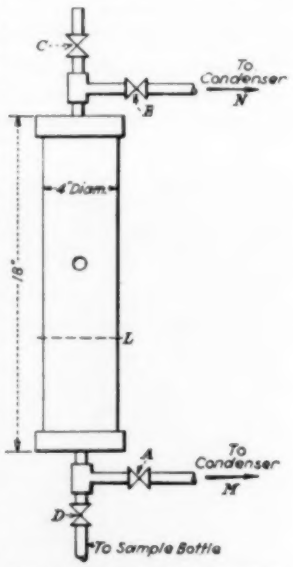

Fig. 8 Pressure-Equalizing Device

(With *N-M* connections made valves *C-D* are closed and *A-B* opened. Water is allowed to circulate through the container *O* for several minutes and then valves *A-B* are closed.

To draw off a sample for determining the O_2 content valve *C* is opened to break the vacuum, then valve *D* is opened to allow the water to overflow a sample bottle until the level in *O* has dropped about 1/3 of its depth [*L* in sketch], then the bottle is corked.)

In carrying out the various alterations necessary to produce a change in the condition of the circulating water or its flow it should be definitely understood that only one alteration on a particular installation may be made at one time and its results recorded. If more than one alteration at a time is made the cause of any change in results cannot be definitely established.

Increased Kilowatt Output of Adjustable-Blade Propeller Turbines

By C. R. MARTIN,[1] MILWAUKEE, WIS.

The commercial development of the adjustable-blade propeller-type hydraulic-turbine runner has been in a slow and careful manner, with the idea first of solving its mechanical difficulties and later of taking full advantage of the possibilities of high efficiency. The principal problem of the engineer in introducing a new design is to keep to a safe and reasonable program of development such as will not incur serious financial losses. In addition to the mechanical difficulties of the adjustable runner, there also have been many problems of regulation to be solved as well as the determination of a correct design of draft tube. This paper covers the gradual development and placing in service of the adjustable-blade runner in the United States to the time when the European design of automatic adjustable-blade runner was brought to this country.

The objectionable feature of the fixed-blade type of propeller runner is the peaked efficiency curve and the low efficiency at part-gate openings. By adjusting the runner blades one can operate at all the peak points of efficiency, reducing the disadvantage of part-gate operation. It is now possible to obtain a peak efficiency on a propeller-type runner that is within 1 to 2 per cent of the peak efficiency of Francis-turbine runners. The blades of a Francis runner are not adjustable, resulting in one-peak efficiency. The adjustable runner, therefore, with the possibility of adjusting its peak over a considerable range in load, makes it possible to obtain an average plant efficiency as high as that of the Francis runner.

THE adjustable-blade propeller-type hydraulic-turbine runner has been generally recognized during the last year as representing a marked advance in hydraulic-turbine design. The commercial application of the adjustable-blade runner dates back for several years, both in this country and in Europe. However, it is only within comparatively recent years that more than one manufacturer in the United States was in a position to enter into contract for this type of equipment. The development has been slowly and carefully made in order to determine the best design and method of operation for obtaining the maximum kilowatt-hour output with the adjustable-blade propeller-type runner.

Early in the history of the propeller runner, Forrest Nagler[2] determined many of the characteristics of adjustable-blade propeller runners. This work was accomplished by building runners with different tilts of blades which gave the essential hydraulic characteristics of a runner with flat and steep blade settings. The difficulties in building an adjustable-blade runner of sufficient strength for commercial operation were considered too great at that time, and nothing further was done toward solving the problem until 1917. At that time J. F. Roberts[3] produced a design of an adjustable-blade propeller-type runner which was considered acceptable for manufacturing purposes. The World War intervened, and the work of commercial application was delayed until 1920.

The principle of vane adjustment has been appreciated for many years, as is evident by pump impellers used by the Sanitary District of Chicago at the Thirty-ninth Street Station and installed in 1904. Fig. 1 shows a sketch of the construction used on these propellers. The vanes were made with a flange with slotted bolt holes so that the tilt could be increased or decreased to vary the quantity of water pumped and the head against which the pump operated. It is interesting to note that screw pumps made with vanes similar to those employed in the propeller-type-runner turbine were installed as early as 1888.

In 1921 and 1922 there were a large number of installations made with propeller-type runners. Among these was the Green Island Plant, purchased by the Ford Motor Company for an installation at Troy, N. Y. Fig. 2 shows the runners as furnished with these turbines. It is to be noticed that the runner blade and hub are made in four parts, and so far as is known to the author, this is the first installation in the United States of a separate-blade axial-flow turbine runner.

Shortly afterward the Northern New York Utilities Company purchased for the Sewell's Island Plant two adjustable-blade-runner turbines which required that the unit be shut down and the flume unwatered in order to make an adjustment of the runner vanes. A sketch is shown, Fig. 3, which will illustrate the construction used on these runners. In 1924 the Inca Mining Company purchased an adjustable-blade runner which had blades bolted to the hub. This was a comparatively small runner, and slots were left in the runner flange for bolting the blades to the hub and for adjusting the angle of the runner blade.

The first commercial application in America of the adjustable-blade propeller-type runner where the blades could be moved from the turbine pit, and without requiring that the flume be unwatered, was built in 1925. The adjustment was made by means of the Henderson arrangement, U. S. Patent No. 1699499, which consisted of an adjusting mechanism located between the turbine and generator-shaft flanges. The design included a method for locking each runner blade securely in the runner hub to insure that the runner blade could not rock back and forth in the hub due to changeable vacuum conditions in the high-efficiency draft tubes.

The foregoing gives a brief history of the adjustable-blade runner in the United States prior to the advent of the automatic adjustable-blade runner. Each successive step in the development has been made with the idea of retaining the element of rigidity. The success of the runner has been demonstrated, and is being proved by every-day operation. The question of how far the adjustable feature can be used in solving present-day requirements and the various devices employed in its adaptation will be the interesting work of the future. It is logical that more trouble will be experienced with pitting of propeller-type runner

---

blades[4] than has resulted with various types of Francis runners. Five years' experience involving 32 units of capacities varying from 400 to 12,000 hp. and for heads from 8 to 33 ft. shows no serious pitting difficulties with adjustable-vane runners. There have been no mechanical difficulties in connection with the adjusting mechanisms. However, as the vanes are automatically adjusted the likelihood of pitting will probably increase, and greater expense should be incurred in protecting the runner blades against this action of the water.

The characteristic of the higher-speed fixed-blade propeller-type runner (N_S about 150) is such that the shape of the efficiency curve is more peaked than with any other type of hydraulic-turbine runner. A group of curves, Fig. 4, illustrates how the shape changes from a comparatively flat to a much steeper curve for a range of specific speed from the impulse wheel at 4½ specific speed to the propeller wheel with its specific speed of 200 or more. It was this low efficiency at part-gate position compared to the higher efficiency of the Francis runner which led to the early experiment of Mr. Nagler, and it was found at that time that the solution hydraulically lay in the adjustable-blade runner.

The first Holyoke check of the adjustable-blade runner was made in May, 1923, Holyoke test Nos. 2904–6–7–8–9. Results of this test are shown on the curve sheet, Fig. 5, and represent the horsepowers and efficiencies plotted for a unit speed of 340 r.p.m. The horsepower figures have been reduced to represent the power that could be obtained on a 10-in.-diameter runner under 1-ft. head. This curve is intended as an illustration only of the results that can be obtained by adjusting the blades of a propeller-type runner and is not intended to show present-day runner characteristics. Each of the five curves represents an efficiency test with the blades set in a fixed position, at the unit speed of 340 r.p.m. The dotted line drawn across the top of this curve represents an envelope of maximum-efficiency points that could be obtained by an infinite number of runner-blade adjustments. Reading from left to right, the five curves show an increased angle of runner-blade tilt. The first curve represents the runner blade set in almost a horizontal position. The other curves represent a tilt of from 5 to 7½ deg. each from the horizontal, or additional tilt below the flat setting. The total angularity of movement as covered by the curves was approximately 22½ deg. On this runner an efficiency of 88½ per cent was obtained at the best point and at a horsepower of 0.168. Assuming full load as the maximum point of efficiency under the maximum runner tilt, then the full-load horsepower of this runner is 0.26, with an efficiency of 82 per cent. With this horsepower rating of 0.26 the efficiency at half load was 86 per cent. The difference in efficiencies between the various curves and the dotted line, which is the envelope curve, shows the gain in efficiency that can be obtained with the adjustable-blade runner. If this design of runner was used with runner blades cast integral with the hub and set in a fixed position, the maximum horsepower rating for best efficiency would be limited to 0.18 hp. One of the striking features of the adjustable-blade runner is that one of the same diameter as a fixed-blade runner can be rated approximately one-third greater in horsepower. Generally speaking, the efficiency of a fixed-blade propeller-type runner is 65 per cent at half-load. That of an adjustable-blade-runner at half-load is 86 per cent.

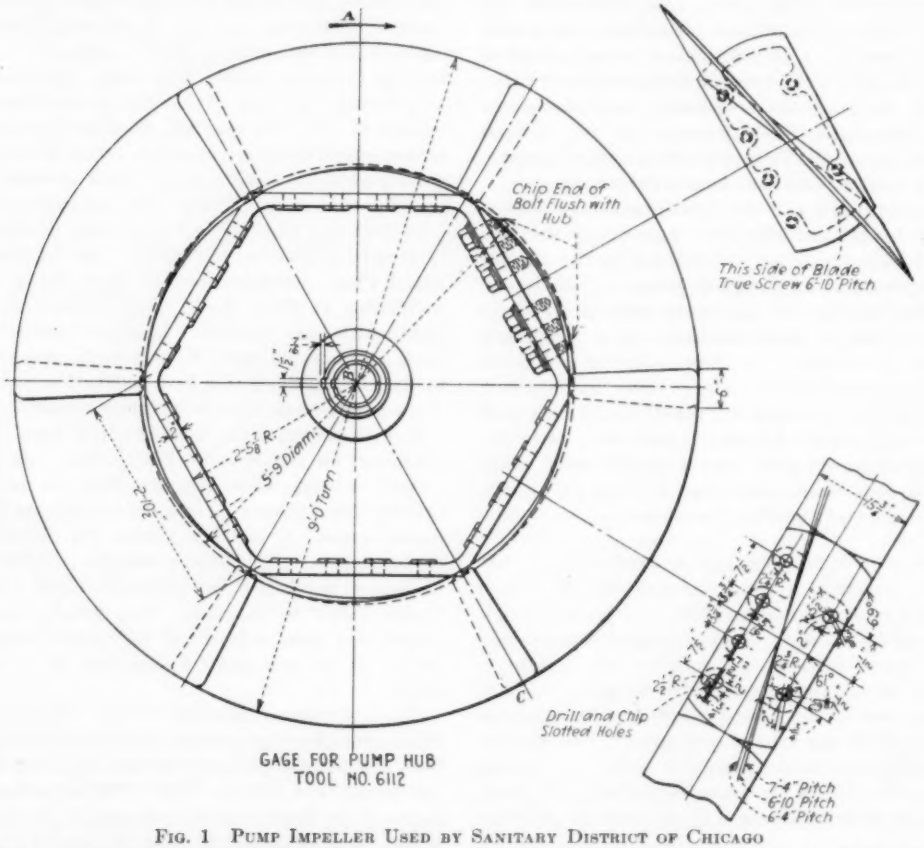

FIG. 1 PUMP IMPELLER USED BY SANITARY DISTRICT OF CHICAGO
(This impeller was used with an axial-flow type of pump operating against an effective head of 7 to 11 ft. and delivering 600 to 700 c.f.s.)

[4] See Trans. A.S.M.E., 1929, Paper HYD-51-9, "Permissible Suction Head of High-Speed Propeller Turbines," by Arnold Pfau.

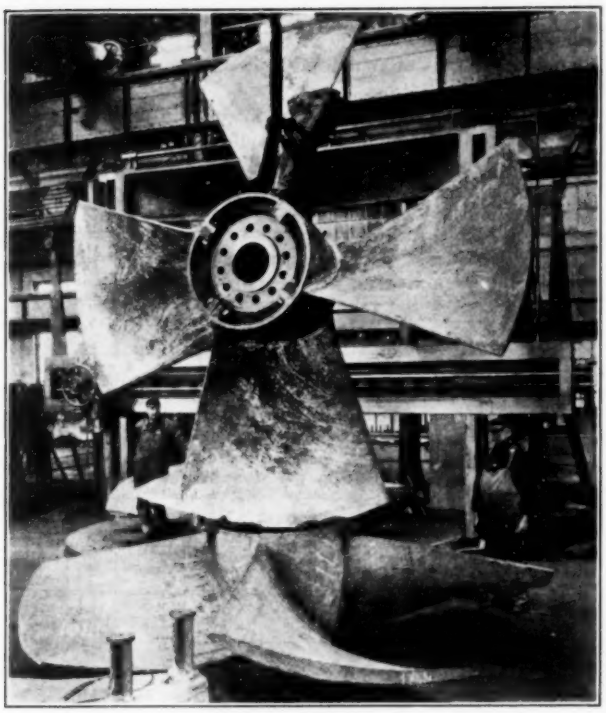

FIG. 2 FIXED-BLADE PROPELLER-TYPE TURBINE

(Each blade is made as a separate part. This turbine is used with a single-runner vertical-shaft hydraulic turbine to develop 2000 hp. under 13 ft. effective head, at a speed of 80 r.p.m. The runner diameter was 156 in. and the assembled weight 17,000 lb. The runner was made of cast steel.)

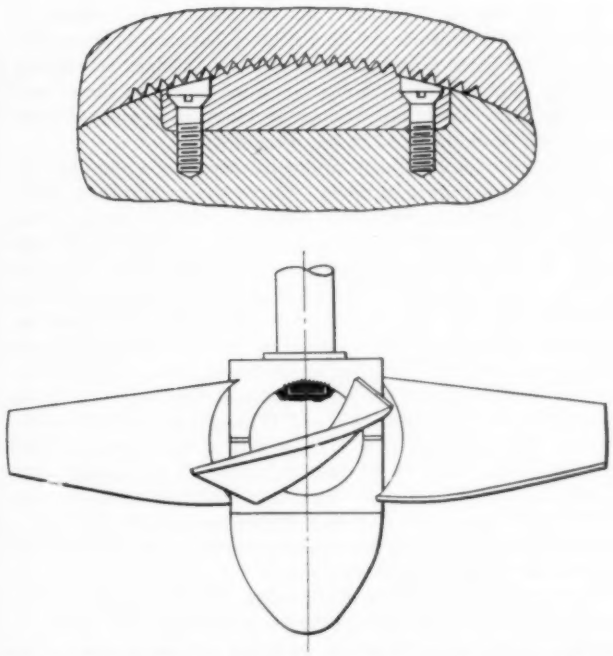

FIG. 3 EARLY DESIGN OF ADJUSTABLE-BLADE PROPELLER-TYPE RUNNER

(The runner hub is divided at the horizontal center line, and the adjustment is accomplished by dropping the lower part of the hub, together with the vanes. Each vane is tilted by an amount of one or more teeth in the adjusting block. At the time when this runner was built the problem of smooth operation had not been completely solved, and large pulsations in draft tubes were quite common. It was thought at that time that the runner blade must be securely locked in the hub; later experience has shown that this feature requires very careful consideration.)

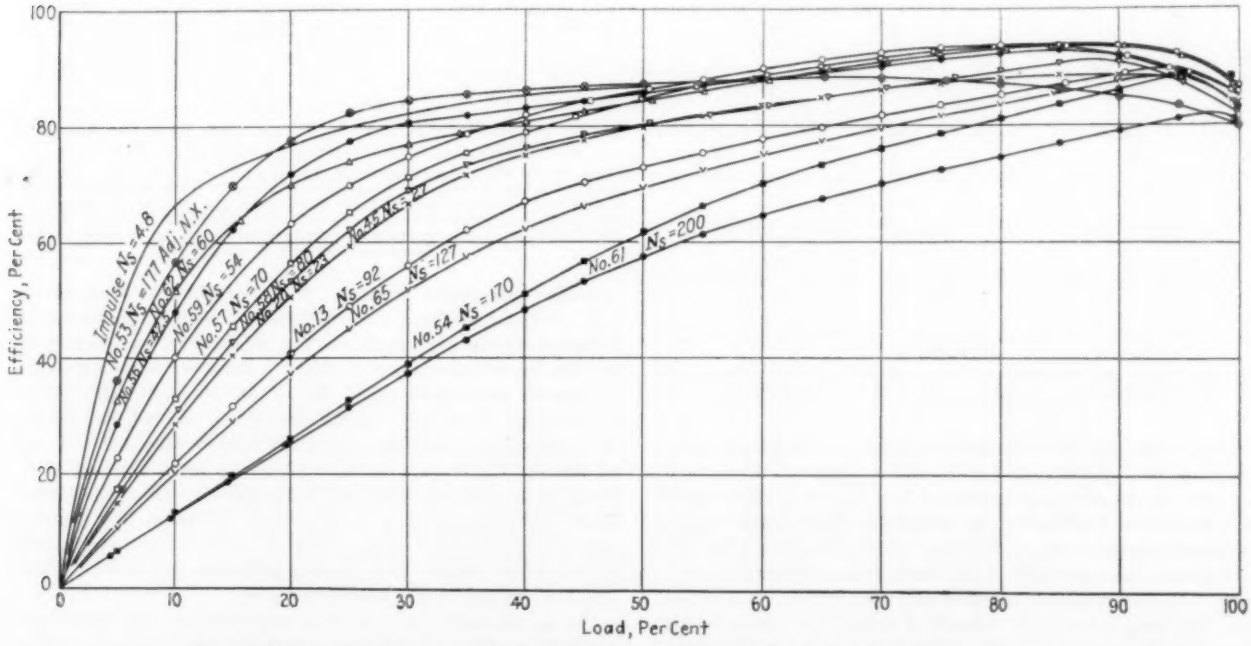

FIG. 4 EFFICIENCY CURVES FOR HYDRAULIC-TURBINE RUNNERS OF DIFFERENT SPECIFIC SPEEDS

(The peaked efficiency curve of the fixed-blade propeller-type turbine falls in line with the efficiency curves of lower-specific-speed hydraulic-turbine runners. The impulse wheel has the flattest type of efficiency curve, with a specific speed of approximately 4½ for best efficiency. At an increase of the specific speed on the Francis type of runner, the efficiency curves become less flat. A corresponding decrease in the flatness of the efficiency curves is found from the Francis runner to the fixed-blade-propeller type of runner; however, the adjustable-blade propeller runner gives a curve which approximates the flatness of the impulse wheel.)

In order best to show the value of the increased efficiency, Figs. 6, 7, and 8 illustrate the efficiencies of four fixed-blade-runner turbines and three adjustable-blade-runner turbines consuming the same total water flow under the same head and the output from the four fixed-blade-runner turbines as compared with the three adjustable-blade-runner machines.

Fig. 7 shows the combined turbine efficiencies of a plant having four fixed-blade-runner turbines. Curve 1 is an efficiency curve of one machine operating alone; curve 2 is the efficiency of two machines, each equally loaded at all times; curve 3 is the efficiency of three machines equally loaded; and curve 4 of four machines equally loaded. The efficiencies are all plotted against brake horsepower. To this sheet have been added the discharge and head curves, based on the recorded flow and headwater variation of the Des Moines River at Ottumwa, Iowa. In addition to the low efficiencies at part-gate openings, this curve also shows that, with a flow between 1150 and 1375 second-feet, there is no gain in output to the plant. Also with a flow between 2200 and 2350 c.f.s., there is no gain in output of the plant. The fixed-blade-runner turbines have therefore two inherent disadvantages—namely, that of low efficiencies at part-gate openings and that of not being able advantageously to use all of the low flow of the stream in producing power.

Fig. 8 represents a series of efficiency, effective-head, and discharge curves plotted against brake horsepower for three adjustable-blade-runner turbines, utilizing the same maximum quantity of water as could be used with the four fixed-blade-runner turbines. The horsepower developed with the three adjustable-blade machines is greater than with the four fixed-blade-runner turbines due to the higher full-load efficiency of the adjustable-runner units. It is to be specially noticed that the

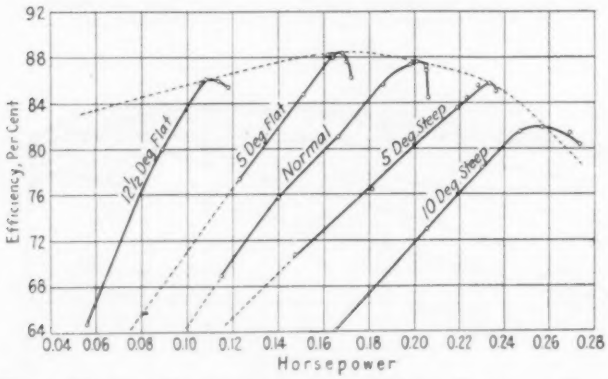

FIG. 5 HOLYOKE TEST OF AN ADJUSTABLE-BLADE PROPELLER-TYPE RUNNER

(The horsepower and speed characteristics of this runner as shown on the curve have been reduced to the equivalent of a 10-in.-diameter runner under 1 ft. head.)

discharge curve for the adjustable-blade-runner machine is almost a continuous uniform curve without any gaps. This is to be expected, as the efficiency curves all overlap, or in other words, the efficiency at half-load on an adjustable-blade-runner turbine is somewhat greater than at full load, which is in accordance with the inherent characteristics of adjustable-blade runners.

Fig. 6 shows a standard duration and head curve. In addition, there has been added the theoretical horsepower output; also the output from the three adjustable-blade runners as determined from the characteristics as shown in Fig. 8 and the output from the four fixed-blade runners as determined from the characteristics as shown in Fig. 7. The gain in output of the three adjustable- over the four fixed-blade-runner machines, as determined by the power-output curves of Fig. 6, is equal to 1,341,232 b.hp-hr.

The actual output of three adjustable-blade-runner turbines equals 22,600,000 b.hp-hr.

The actual output of four fixed-blade-runner turbines equals 21,258,768 b.hp-hr.

This shows a gain of 6.3 per cent increase in output for the three adjustable-blade runners. It should be noticed that in the example given the diameter of each of the four fixed-blade-runner turbines is the same as the diameter for each of the three ad-

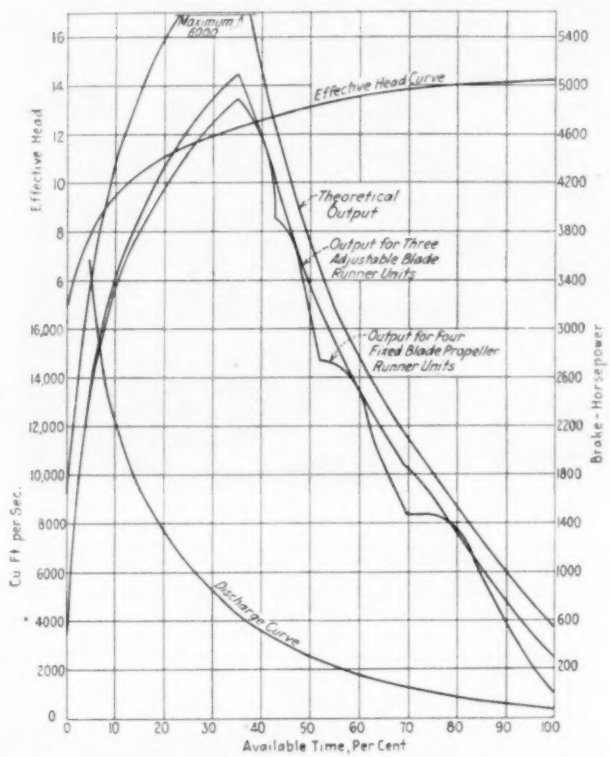

FIG. 6 STANDARD DURATION AND HEAD CURVE, WITH THE ADDITION OF GRAPHICAL REPRESENTATION OF THEORETICAL OUTPUT

(This shows the output for three adjustable-blade-runner units and the output for four fixed-blade propeller-runner units. The increased brake-horsepower output of the adjustable-blade-runner units over the output for four fixed-blade-propeller-runner units is 1,341,232 b.hp-hr., or approximately 950,000 kw-hr. This increase represents a gain of 6³/₁₀ per cent for the adjustable-blade-runner units.)

justable-blade-runner turbines. If draft tubes were built on the basis of linear proportion to the runner diameter, the width of flumes would be the same for the adjustable-blade-runner as for the fixed-blade-runner turbines. However, it is necessary to furnish somewhat wider flumes for the adjustable-blade-runner draft tubes than for the fixed-blade turbine, due to the fact that unless sufficient draft-tube area is provided with an adjustable-blade-runner turbine, a point is reached where additional water discharged through the turbine by tilting the runner blades downward creates such a large discharge loss that no gain in power results. This brings up a very important feature in draft-tube design—namely, that sufficient area must be provided to eliminate high backwater losses.

During the past five or six years considerable data have been obtained in the use of the adjustable-blade runner. Some of these experiences illustrate the advantages of that type of runner, and some features which should be given further consideration.

One of the early plants consisted of three 1200-hp. units, under 9 ft. head, which replaced a number of vertical turbines, gear-connected to a horizontal generator. The output from the

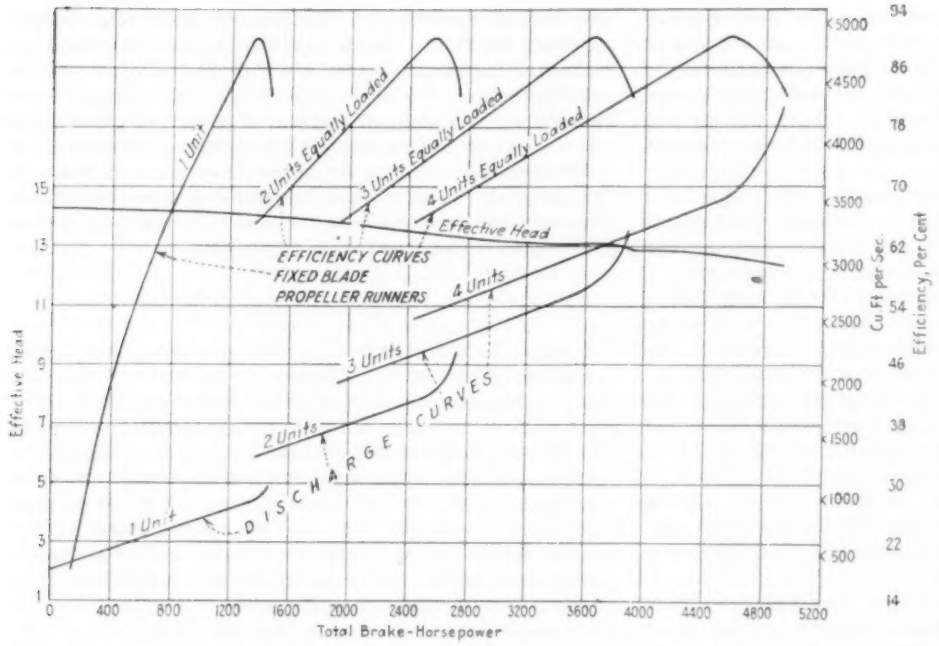

FIG. 7 EFFICIENCY, DISCHARGE, AND EFFECTIVE-HEAD CURVES PLOTTED AGAINST TOTAL BRAKE-HORSEPOWER

(This shows the efficiency of a fixed-blade propeller-type-runner plant for all conditions of discharge up to its full capacity. Notice the gaps between the discharge curves for one and two and for two and three units. These gaps represent portions of the flow which cannot be utilized by the fixed-blade-propeller runners.)

such as occur during heavy floods, a point finally is reached beyond which the power output of the turbine decreases much faster than the ratio of the three-halves power of the heads. In other words, for a runner with a given blade tilt, as the head decreases the unit speed of that runner increases until runaway speed is reached, at which speed the runner no longer produces power. If the blade tilt of the runner is flattened, the runaway speed is increased; in other words, the head can be reduced still more before the unit speed of the runner reaches the runaway speed. It would be desirable to design the runner for opposite conditions so that increasing the runner tilt would increase the runaway speed. Unfortunately, however, this type of runner does not lend itself to such a feature of design. In the adjustable-blade-runner design this inherent disadvantage, during high backwater and resulting low-head conditions, can be offset by flattening the runner-blade tilt and thus improving the runner-speed characteristics.

vertical-gear-connected units averaged 8,000,000 kw-hr. The output from the adjustable-blade-runner plant, which utilized the same water and which was set in the same overall width of power house, has exceeded 12,000,000 kw-hr. per year. The increased output has been due both to the greater installed capacity and higher overall efficiency. The plant in question receives its water from a large lake with regulated discharge, and the runner blades are set, generally speaking, on Monday morning for a definite flow, and they operate for the week under this flow condition. There is practically no change in runner-blade setting during the week, except to regulate for a sudden heavy rainfall or some other requirement of lake-level regulation. One year later four 1100-hp. units, under 8½ ft. head, were installed on the same river. This later plant was an entirely new development, but was limited as to width of power house. However, the same condition of fixed flow prevailed throughout the week. During the spring floods they are troubled with excessive backwater, and it was found that during these periods the output of the plant under a head of 3 and 4 ft. was increased materially by flattening the runner blades from the full-tilt position.

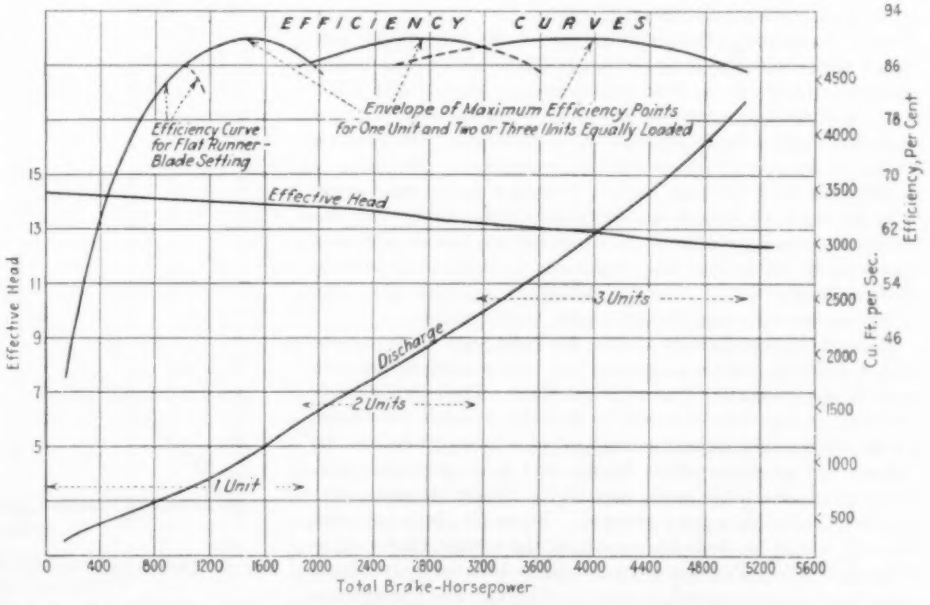

FIG. 8 EFFICIENCY, DISCHARGE, AND HEAD CURVES PLOTTED AGAINST TOTAL HORSEPOWER FOR THREE ADJUSTABLE-BLADE-RUNNER TURBINES

(These turbines are able to utilize over 90 per cent of the flow within the plant capacity, with an average efficiency of approximately 88½ per cent.)

This is due to the fact that with extreme head reductions

Another example of an adjustable-blade-runner installation is a plant consisting of three 3750-hp. turbines under 28-ft. head. This plant operates as a run-of-river plant, using the water as it comes down the river. Immediately downstream from this plant are three high-specific-speed Francis-runner turbines which

were installed at essentially the same time. In checking plant records it is found that during low-flow periods a greater output is obtained per foot of head on the adjustable-blade-runner installation than can be obtained from the high-specific-speed Francis-runner installation. These plants clearly demonstrate the advantage of the increased efficiency that can be obtained at the flat runner-blade positions.

A plant consisting of six 5000-hp. units, at 30 ft. head, was equipped with adjustable-blade-runner turbines. This plant, after operating for a period of more than one year, finds that the adjustable-blade runner gives them the following advantages:

1 The additional capacity that can be obtained by tilting the runner blades enables them to keep one unit as a spare. This is very important, as they are very apt to have some difficulty with the electrical apparatus during storm conditions.

2 This plant operates from a storage reservoir and the load is fixed from day to day, the load being changed by varying the number of units except during the high-flood periods. During the night, or from 10 p.m. to 6 a.m., it is not desirable to carry a great amount of load on the hydro system. During this period one of the units has its runner blades set to a flat position, and only sufficient power is delivered to the system as is required for regulation purposes.

3 The increased capacity which can be obtained by more steeply tilting the runner blades increases their peak-load output from a normal operating load of 3000 kw. per unit to a maximum of 4000 kw. The capacity of the plant normally is from 16,000 to 18,000 kw. This capacity has been increased to 23,000 kw. under flood-water condition, and when called upon to carry maximum peak load under full operating head, the peak capacity could be increased to 24,000 or 25,000 kw.

In a recent plant the requirements of the adjustable-blade runner were limited to using the runner-blade tilt for maintaining constant capacity as the head was decreased due to floods. The capacity of the generator was limited to the capacity of the wheel at most efficient blade setting. It is questioned whether this saving in generator cost is justified, considering the value of generator capacity for peak loads. There is a case in mind where it is proposed to furnish an adjustable-blade-runner unit for 2000 kw. capacity, under 21 ft. head, but to provide sufficient runner-blade tilt so that this output can be maintained with an effective head of 15 ft. This is a rather extreme case, but it can be met successfully with the adjustable-blade runner.

Most of the installations that so far have been made operate with a controlled water supply, or the load conditions are such that the blades can be adjusted at any time. The plants already discussed require that the unit be shut down before the blades are adjusted. The adjusting mechanism is located between the turbine and generator shaft flanges and is so arranged that, after the adjustment is made, each of the runner blades is automatically locked in a fixed position. No doubt there are cases where it would be desirable to adjust the runner blades automatically without shutting down the unit. Isolated hydro plants must be adapted to control the speed. This involves a sacrifice in efficiency which is unavoidable due to the variation of the output. Here regulation is of greater importance than the maintenance of highest overall efficiency. By far the greater number of low-head plants in this country are a part of a power system which has additional plants, hydro or steam, operating in parallel, to take care of the fluctuating load. The low-head plant usually can be operated from the point of view of obtaining highest overall efficiency, thereby justifying such refinements in the interrelation of guide-vane opening and runner tilt as will produce the best economy for each respective operating head. More and more of the streams are being regulated, and as time goes on, the point of complete regulation will no doubt be reached on the principal power streams. The disadvantage of automatically regulating the runner vanes, especially in connection with the guide-vane movement, is that it is difficult to lock the blades after the change. The period is just being entered of adjustable-blade-runner use, and new features of design will open up as this new type of runner is employed in more actual developments.

The hydraulic utility of the adjustable-vane runner has been demonstrated. However, the unwarranted number of fixed-blade-runner failures points to the need of even greater caution in extending the adjustable-vane-runner field.

Discussion

CARROLL F. MERRIAM.[5] The author presented some interesting curves indicating the comparative operating efficiency of plants having all fixed-blade propeller turbines and all movable-blade propeller turbines; but it would be interesting to consider the effect of combining these two types of units in a single plant. To illustrate the promising possibilities in this respect, the writer has assumed as an example a broad efficiency curve that might be expected for a movable-blade unit, such as the author has described, and an efficiency curve that might be expected for one having fixed blades. In order to simplify comparison, these curves have been drawn to have the same maximum efficiency and the same output and discharge at maximum load.

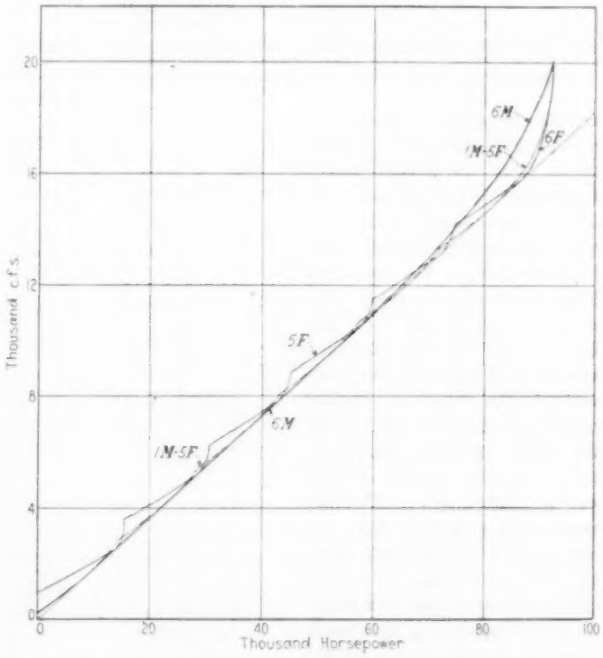

FIG. 9 DISCHARGE VERSUS HORSEPOWER—NO ALLOWANCE FOR RUNNING SPARE CAPACITY

On the accompanying diagram, Fig. 9, there have been plotted curves marked 6-*F* and 6-*M*, showing discharge versus horsepower, for plants having six units each of both types of wheels. These curves correspond to those which are shown by the author in Figs. 7 and 8. There has been added a similar curve marked 1*M*-5*F*, for a plant having one adjustable and five fixed-blade turbines.

It has been pointed out by the author that the objectionable feature of having all fixed-blade units is the presence of inefficient

[5] Pennsylvania Water & Power Company, Baltimore, Md. Mem. A.S.M.E.

zones or gaps between the curves for successive groups of units. These zones are almost entirely closed by the use of movable-blade units. It should be noticed, however, that the substitution of one movable-blade unit for one having fixed blades eliminates the greatest portion of these areas, and also that successive substitution would have little further effect. The fixed-blade units can secure better efficiency than the movable when the available water is nearly equal to the full capacity of the plant. The substitution of one movable-blade turbine may somewhat reduce this advantage, but by no means in proportion to the gain from increased efficiency at lighter total station loads.

One distinct advantage in the fixed-blade propeller turbine, as compared with the movable blades, is the lower first cost. For this reason, it is very desirable to design hydro power plants in which either type might be used, to secure the maximum benefits which are commensurate with the additional cost of movable-blade over fixed-blade units.

Another important element to be considered is the amount of running spare capacity required for system protection, which frequently makes it necessary to add another unit, even though the actual load could be carried more efficiently without the additional machine. When it is necessary to make liberal allowance for heavy swings or for sudden failure of the largest machine on the system, it may be found economical to select more units of the movable type. Fig. 10 has been drawn up to show the

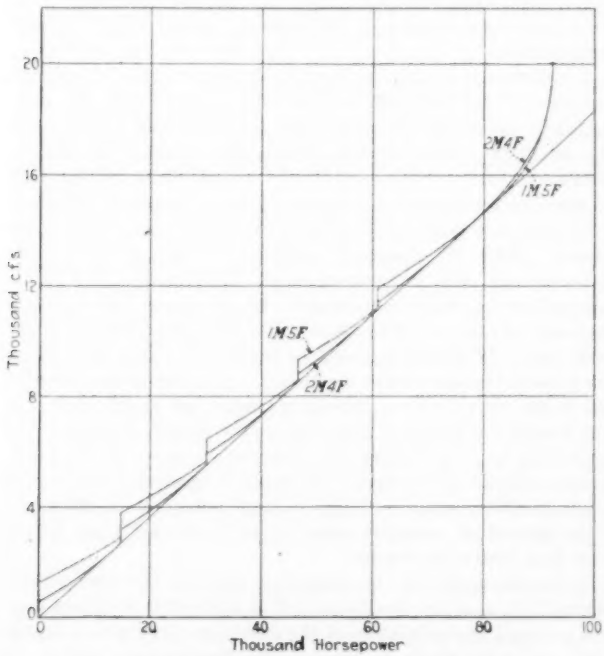

FIG. 10 DISCHARGE VERSUS HORSEPOWER—11,000-HP. ALLOWANCE FOR RUNNING SPARE CAPACITY

comparison between discharge versus output curves for two six-unit plants with one and two movable-blade units, respectively. It will be seen that in the case of the former there still remain large inefficient gaps which can for the most part be closed by a second movable-blade machine.

ROBERT W. ANGUS.[6] This valuable paper calls attention to the use of the propeller-type turbine with adjustable blades as distinguished from the corresponding turbine with fixed blades. If the blades of the propeller-type runner are adjusted to suit the load or head, or both, very much flatter efficiency curves are obtained than are possible with the fixed-blade propeller units; and the author shows in Fig. 4 that under lower loads the efficiency of the adjustable unit is better than that of Francis units, although these types change places at full load.

The author appears to have based his conclusions in the paper on the turbine always running at its best efficiency, which implies that the blade adjustment is always made to suit the power and head available. Such a condition is only possible, however, if the blades are automatically adjustable during the operation of the turbine and are therefore adjusted by the governor and not by hand. It is evident that if the machine has to be shut down to make the adjustment, or even if the adjustment must be made by hand while the machine is running, the results shown in the paper will not be correct, because under such conditions the machine will not always run at best adjustment. Hand adjustment is very valuable in looking after changes of head due to floods, etc., as the adjustment need only be made at intervals.

The automatically adjustable propeller turbine, or Kaplan turbine as it is commonly called, has been very slow in making headway in this country and, so far as the writer knows, only one manufacturer now has the rights to make this type of turbine in America. On the other hand, when the writer made a very extensive trip to the hydraulic power plants in Europe last year he found many plants using the Kaplan turbine, and the number of such turbines is relatively increasing, although the earliest units have not been in use for many years. Since different servomotors are in use on the distributor and runner guides, the relation between the movements of the two sets of guides may be altered if it should be necessary to meet requirements of varying heads, speeds, etc., and usually the adjustment of the runner blades is much slower than the distributor guides.

An inspection of the mechanism necessary to operate the runner blades indicates that it is not altogether simple, and the Kaplan turbine is more complicated than the simple propeller turbine. For power plants with fixed heads and for which the propeller type of turbine is suitable it would therefore be advisable to have some of the units with fixed runner blades and to operate these continuously at the load corresponding to best efficiency, while some Kaplan turbines could be installed to take up the variations in load. Such a plan would give the simplest units, while at the same time producing maximum efficiency and long life of the turbines. If the head has large variations, naturally all but the Kaplan turbines would have hand-adjustable blades.

One of the most interesting plants now being built for a low head is that at Ryburg-Schworstadt on the Rhine River a short distance east of Basel. This plant connects the German and Swiss frontiers, and the fact that the two countries were involved probably accounts for some novel features connected with it. The weir is on the Swiss side and the power house and transformer station are on the German side of the river, and the designs are for four vertical turbines of 35,000 hp. each, although the output falls to about one-half of this for the lower heads.

Since the units are of unusually large size, considering the head of 35 ft., requiring about 10,000 c.f.s. each, there was a special engineering organization entered into for the construction of the turbines, three of the largest turbine builders in Europe forming a joint company for the purpose. All of the units are to be vertical Kaplan turbines with a runner diameter of nearly 23 ft., so that when completed the plant will be of unusual interest, and the results from it will be of great value in connection with this type of turbine. The information available shows that the draft-tube diameter at the top is 23 ft., and hence the vertical

[6] Professor of Mechanical Engineering, University of Toronto, Toronto, Ont., Canada. Mem. A.S.M.E.

component of the velocity at full load is slightly over 24 ft. per sec., the corresponding velocity head being 9 ft., or 25.7 per cent of the head of 35 ft. It is interesting to note that quarter-turn draft tubes are being used and that the runners are set at approximately normal tailwater level.

The paper is of real value in laying stress on a type of turbine which is essential to the success of many low-head plants.

ARNOLD PFAU.[7] The author, in the closing paragraphs of his able paper, points out that automatic adjustment of the runner blades would be desirable in certain cases, particularly with isolated plants which must be adapted to control the speeds.

He points out that this involves a sacrifice of efficiency. May the writer be permitted to dwell a little on this particular point? Where speed control is of importance, efficiency must take a secondary place. Vice versa, where maximum kilowatt output is the prime requirement, the speed control is of secondary importance. Thus it becomes evident that, in the first case, automatic control of guide vanes by the governor for quick adjustment of the output in accordance with the load change and of runner blades for maintaining as high as possible an efficiency should be adopted, whereas the second case justifies a refinement in the interrelation of guide-vane opening and runner tilt, for the purpose of obtaining highest economy for each respective operating head.

For a fixed head the law of interrelation between guide-vane opening and runner-blade tilt is a fixed one for obtaining the envelope of maximum efficiencies. This law, however, varies as the head varies, unless the speed can be changed accordingly, which, however, is commercially impossible. It is therefore evident that the fixed interrelation obtained with governor control cannot result in highest economy under variable heads, whereas an individual adjustment of the runner blades permits of such a refinement, so that a substantial increase in kilowatt output can be obtained during each extended period of existing operating head.

GEORGE A. JESSOP[8] AND BEAUCHAMP A. SMITH.[9] The author has called attention to what, at the present time, is the most interesting and important development in the hydraulic-turbine field.

The first known instance of the attempt to use an adjustable-blade turbine is the Ludlow United States patent No. 67,994, granted in 1867. In this design the blades only were adjustable. There were no water-control gates on the turbine, but stationary guide vanes were used.

About the time the Ludlow design was brought out, there were also many patents issued showing axial flow runners with adjustable gates of the cylinder, wicket, and other types. Apparently the advantage to be obtained by adjusting the buckets and the gates simultaneously to maintain a predetermined relationship was not realized, and no attempt was made to design or build such turbines. The first application of this principle was made by Dr. Victor Kaplan, of Brünn, Czechoslovakia, who entered patent applications in Europe in about 1913 and in this country in 1914. Due to the disturbance in business conditions caused by the war, no attempt apparently was made either in Europe or in this country to make use of the Kaplan designs in a practical way until about 1920. Shortly after this date, a contract was entered into by an European builder for two automatically adjustable-blade units operating under 20-ft. head and developing 100 hp. each. This installation was rapidly followed by others of various capacities and operating under various heads. One European builder alone has furnished 85 turbines of this type developing a total of 187,400 hp. under heads of from 7 to 48 ft. and in sizes up to 40,000 hp. During this same period the same manufacturer has built only 19 fixed-blade axial-flow turbines with a total of 79,000 hp. At the present time European practice is to install automatically adjustable-blade turbines in practically every instance where the head conditions are suitable.

In 1927 exclusive rights under the Kaplan United States patents were secured by an American manufacturer, who immediately proceeded with the commercial development. The first automatically adjustable-blade runner was sold in 1928 and was rapidly followed by other contracts. Since that time 16 adjustable-blade units operating under heads of from 10 to 40 ft. and developing a total of 37,366 hp. have been sold. Of this number only one, and this the first one, has been of the manually adjustable type. It is significant that this last-mentioned turbine has been the means of securing an order for three automatically adjustable-blade turbines for the same installation. It is interesting to note that for this plant, an old one with 20 units now installed, there has been purchased, first, a fixed blade, then a manually adjustable, and now there are on order, as mentioned, three fully automatic adjustable axial-flow turbines.

Sufficient experience has now been had in this country to show that the operation of this type of turbine will be entirely satisfactory.

A study of the author's Fig. 5 will clearly reveal the disadvantages of the manually adjustable compared with the automatically adjustable-blade turbine. As has been pointed out, the envelope shown by the dotted lines shows what can be obtained with an infinite number of runner-blade adjustments. It must be remembered, however, that for maximum efficiency with each gate position there is a definite position of the runner blades. With the manually adjusted turbine, therefore, the envelope can only be approximated. For example, if 0.26 hp. is considered as maximum capacity, let us assume that there are as many as four adjustments made in going from full to 40 per cent load. Of necessity, then, the results will follow the 10-deg. curve until the horsepower is reduced to the maximum shown by the 5-deg. curve, with a consequent large loss in efficiency. If the blades are adjusted when the power output is slightly less than 0.24 hp., the turbine can then be operated on the 5-deg. curve until the maximum power output is reached at the normal blade position, again suffering a large reduction in efficiency. This method of operation must be continued until the 40 per cent load position is reached.

A consideration of the operating features involved clearly shows that, as a practical matter, it is impossible to obtain even the outlined approximation of the envelope curve with a manually adjustable-blade turbine. The turbine can seldom, if ever, be shut down to change the blade position at the exact power output required to obtain maximum economy, thus requiring operation for a longer time on the low efficiency curve. This will cause especially large leases if a margin of power is required for speed regulation.

By using a turbine having automatically adjustable blades which are kept in proper relation to the gates, the results will always follow exactly on the envelope curve shown by the dotted line. The turbine will thus operate with maximum economy without the necessity of shutdowns for adjustment with the consequent expense and reduction in kilowatt-hour output.

Referring to Fig. 6, it may be noticed that the curve showing the output for the three adjustable-blade turbines can be obtained only if the adjustment is fully automatic, and the best

[7] Consulting Engineer, Allis-Chalmers Mfg. Co., Milwaukee, Wis. Mem. A.S.M.E.

[8] Chief Engineer, S. Morgan Smith Company, York, Pa.

[9] Secretary, S. Morgan Smith Company, York, Pa. Jun. A.S.M.E.

that can be done with the manually adjustable turbine is an approximation of the results shown.

A careful comparison shows that the cost of a medium size, fully automatic adjustable turbine is about 6 per cent more than for a properly designed manually operated turbine. This difference in cost increases somewhat for smaller sizes and decreases somewhat for large sizes. In either design, the hub mechanism should be of the same rigidity and strength. The additional equipment required for the fully automatic adjustable type is simple in design and construction and is accessible for inspection and care.

The author has suggested that it is necessary to lock the blades in a fixed position to prevent any possibility of rocking back and forth. Properly designed blades have the operating and supporting stem so placed that the forces on each side of the stem are practically balanced. Just as the governor holds the wicket gates in a fixed position, even against a large unbalanced pressure, so the blades are held in the proper position by the runner servomotor, which is controlled by a distributing valve connected to the gate mechanism and a compensating mechanism between the runner servomotor piston and this valve.

If an adjustable-blade turbine is installed with a larger capacity than would otherwise be used, it follows that the flume must be larger to handle the increased quantity of water without increasing the loss of effective head. The draft tube can always be made to suit the unit spacing required by the flumes. Properly designed elbow draft tubes prevent any possibility of the piling up of water in the tube and thus eliminate all danger of building up back pressure to seriously reduce the effective head on the runner.

The author has suggested that there will be an increased likelihood of pitting with the automatically adjustable-blade turbine.

In our seven years' experience with the fixed-blade turbine not a single case of serious pitting has developed, although the axial-flow turbine has been installed under heads as high as 60 ft.

If the blades are automatically adjusted and kept in the correct relationship with the gates, pitting will be decreased and stability of operation increased, because the gates and buckets are maintained continuously in the proper relationship to produce the best and most efficient conditions of flow. With the manually adjusted runner, the pitting will be reduced to the extent that the flow conditions are improved by the adjustment of the blades.

The fully automatic adjustable turbine has no limitations as to advantageous use only with a controlled water supply nor is it necessary to confine its use to those plants where the operating conditions are such that the unit can be shut down and the blades adjusted at any time.

Operation of modern systems calls for steady loads on the steam plants and variable loads on the hydro plants. The fully automatic adjustable turbine is suitable in every way for such service, whereas the manually adjustable runner has obvious serious disadvantages, if, indeed, it can be used with any economy at all.

It is necessary to state that the S. Morgan Smith Company has exclusive rights under all the United States Kaplan patents. The installations are as follows:

J. W. LINK.[10] In the very interesting paper the author has confined his comments largely to telling the net results of the good points of the adjustable-blade turbine as expressed in kilowatt-hour output, and there is little, if anything, that need be added to this aspect of the case, except to say that the general conclusions seem to be sound.

If a departure from the subject as expressed in the title is permissible, it may be well to bring out some points which, while they may be mentioned or implied in the paper, may not be given the emphasis they deserve.

The propeller-type turbine, but especially the adjustable-blade design, is a distinct contribution to the progress of water-power development. This is particularly important at this time, because of the more or less successful competition of the steam turbine in the field of prime movers.

The propeller-type turbine makes possible the development of some water powers which would otherwise be economically impracticable, but it is not suited for all situations.

The adjustable-blade turbine is peculiarly adapted to very low-head situations, but more especially to those having a large variation in head and water supply, because these machines not only develop more output at part gate, because of better efficiencies, but also because they will continue to turn out power under heads so reduced as to render other types of hydraulic turbines ineffective.

The author has stated that the advantage of the adjustable-blade turbine lies in the increased kilowatt-hour output, combined with lower overall costs. This statement is probably a little too broad, for, while the high specific speed practicable in a propeller-type turbine may tend to reduce the cost of the generator and exciter and in some cases may also tend to reduce the cost of the power house, there are many situations where the dimensions of the power house will be determined by the size of the water passages and there may be no reduction in cost by reason of using the adjustable-blade turbine. If, however, the high specific speed of the propeller turbine should effect a saving in cost of a power development, such saving would probably be produced by the fixed-blade as well as the adjustable-blade turbine.

There are some situations where the generating units can be operated advantageously at fixed loadings, and in such cases a fixed-blade propeller-type turbine would probably give as large an output as the adjustable-blade turbine, and it is probable that the Francis turbine would give a larger output provided the head was practically constant.

However, conditions change, and even if it should be best to operate a plant today under a fixed load, in five or ten years it may be desirable or necessary to operate in some other way; and the great advantage of the adjustable-blade turbine lies in its adaptability to changeable conditions of operation, of head, and of stream flow. In other words, it is a more flexible machine, as regards operating conditions, than any of the other types of hydraulic turbines.

In considering the possible advantages of the adjustable-blade turbine, it should not be forgotten that it has its limitations. In its present state of development it is peculiarly a low-head turbine and probably finds its largest field of usefulness in situations where the head is 30 ft. and under, but especially where there is a large percentage variation of head.

If this machine can be successfully developed for higher heads, it will doubtless have many, if not all, of the advantages that it has for the lower heads, but the maximum range of heads under which it will operate successfully has yet to be determined.

It is also probable that without automatic control of the blade

[10] Hydraulic Engineer, Byllesby Engineering and Management Corporation, Chicago, Ill.

settings the adjustable-blade turbine will be entirely impracticable for use in a plant where full automatic operation is desired.

In plants where it is necessary to vary the load frequently during each 24 hours because of regulating requirements or because of frequent daily fluctuations in water supply, manual adjustment of the turbine blades would be a considerable inconvenience if not an absolute impossibility. There are comparatively few situations where low-head plants would be subjected to such conditions, and if only one or two settings of the blades in 24 hours would be required, manual control would be entirely feasible, because the time required for stopping a machine (if it happens to be loaded when the adjustment is to be made), making the adjustment, starting the machine, and putting it back on the line is only a few minutes.

The author calls attention to progressive stream regulation as favoring the adjustable-blade turbine and voices the optimistic opinion that complete regulation will eventually be a reality on the principal power streams of the country.

This is a consummation devoutly to be wished, but the physical conditions are usually unfavorable to this accomplishment.

However, if complete regulation were accomplished, presumably it would mean constant or nearly constant stream flow and practically uniform head, and such conditions of operation would appear to reduce rather than enhance the advantages of the adjustable-blade turbine.

Author's Closure

Each of the discussions brings out additional features in connection with propeller-type runner turbines. These points can be summarized as follows:

Mr. Merriam's discussion emphasizes the possibility of a combination of adjustable- and fixed-blade runner units in order to effect economies in a power development. From the standpoint of present-day practice this is very probably true, but as we proceed with the development of the adjustable-blade runner it is possible that at some future date we may be able to take full advantage of the adjustable-blade runner and build a plant having all adjustable-blade runners at approximately the same price as could be done with a combination of fixed- and adjustable-blade propeller-type runners.

Under the discussion offered by Mr. Robert W. Angus, Mr. George A. Jessop, and Mr. Beauchamp A. Smith, the advantages of the automatic adjustable-blade runner have been presented as an addition to the paper on the manually adjustable runner. The author's experience has been confined to actual power-plant operating data obtained from the manually adjustable-blade runner. He has, therefore, offered this experience in the hope that it may be of value to the hydraulic engineering profession in the design of power plants involving both manual and automatic adjustable-blade propeller-type turbines.

Mr. Arnold Pfau brings up the very interesting subject of interrelation between guide-vane opening and runner-blade tilt for varying head conditions. This feature of design is the most important point to be considered in connection with the adjustable-blade runner. Generally speaking, each plant that may be built has its own peculiarities of intake- and draft-tube requirements. It is the author's experience that the relation of guide-vane opening to maximum efficiency in the actual plant varies considerably from the relation established in model test flumes. If we are to obtain the peak efficiency on the adjustable-blade runner, we must therefore determine the characteristics of the wheel under the actual power-plant setting.

The discussion of Mr. J. Wm. Link gives an interesting sidelight on the propeller-type turbine from the standpoint of the user. The point of changing conditions under which a hydro plant may be required to operate in future years is certainly a very forceful argument in favor of the adjustable-blade runner.

Changing Requirements in Hydraulic Turbine Speed Regulation

By FORREST NAGLER,[1] MILWAUKEE, WIS.

Flyball control of units such as are now operated in the plants of large systems may be of secondary importance for normal conditions. It is a control for large or sudden changes, a shutdown device for emergency purposes, and it effects certain conveniences in operation. It is of real use only in emergency conditions, it is entirely ineffective when a unit is on the load limit, and it is entirely ineffective when the gate position is controlled by frequency under gradual load change conditions. It comes into play in case of line troubles or when load changes are faster than the frequency control can meet.

Practically complete governing equipment can be built without a large flyball, and with probable ultimate simplification of governing equipment. It would consist of frequency control operating the gate through regulating cylinders and distributing valve, a load limit positioning device for that valve, just as is done nowadays, except that no main-relay connections would be required, no dashpot necessary, and all question of flyball drive eliminated. Emergency stop and emergency start would be obtained simply by making secondary contact at an abnormally high or low frequency point that would take the unit off the line or at least close it to "speed-no-load" condition.

It is not suggested that governors be eliminated. Many of their elements are very satisfactory. The oil-pressure systems now in use are probably the best form of speed-reducing mechanism for the purpose, reducing 600- to 1200-r.p.m. motor speed to as low as 1 r.p.m. It is suggested that they no longer be governors from a normal speed-control standpoint with its possible wide range of gate movement. They should be control mechanisms designed for the duties that they are to accomplish. The design of such controls would rapidly modify governors as they are designed today, and would also begin to modify turbine structures themselves, simplifying and cheapening them, a large portion of their cost being due to details which are not necessary or even desirable for the production of the maximum number of kilowatt-hours for a given stream flow or for a given amount of storage water.

IT IS ADVISABLE in any field of design where conditions change rapidly occasionally to visualize the changing needs and requirements of any particular division of the equipment. Such conditions apparently exist today in connection with speed governors on hydroelectric units. These governors are frequently quite foreign in their action to the main purpose of the plant in which they are installed, being one of the major causes if not the major cause of loss of kilowatt-hours, interruptions to service, damage to parts, and increase of maintenance cost. Conventional governor action is a relic of requirements which no longer exist, as there is no necessity for extensive and continuous gate movement on units of large systems to effect speed control.

The earliest hydraulic unit, probably the earliest prime mover, was connected to a mill stone or water lift. Such a load required no speed control of the water-wheel gates, as the load was of the self-regulating variety to a sufficiently close degree. The same condition existed to some extent in the later mechanical mill drives. When these became electrically driven, a speed control became necessary because of parallel operation and voltage regulation. When various electrically driven mills were first

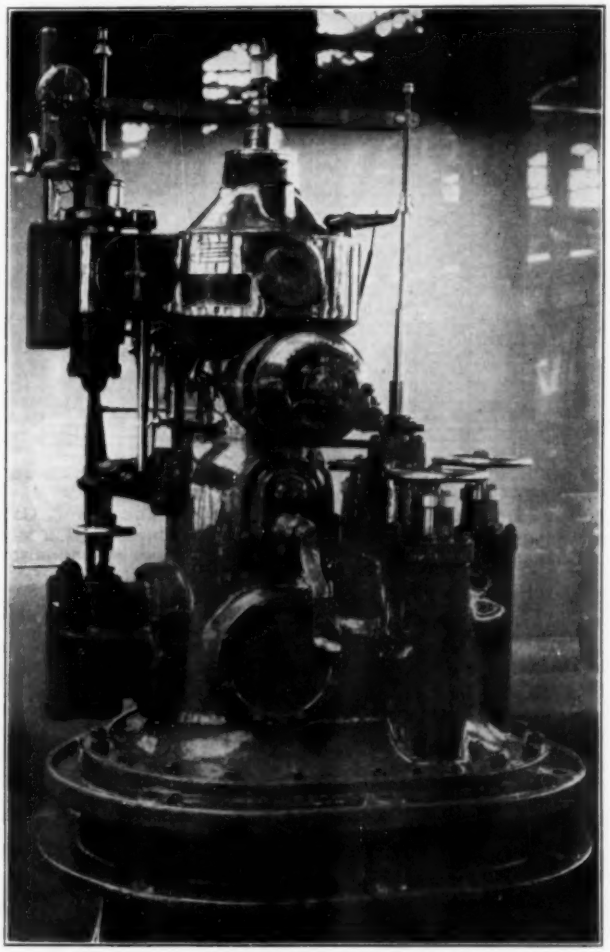

FIG. 1 MODERN ARRANGEMENT OF HYDRAULIC-TURBINE GOVERNOR WITH MOTOR-DRIVEN FLYBALL AND FULL AUTOMATIC ATTACHMENTS. ONE OF EIGHT REGULATING THE 13,000-HP. PROPELLER TYPE UNITS IN OHIO RIVER PLANT OF LOUISVILLE HYDRO-ELECTRIC CO.

(There are two schools of designers of governors. One considers the governor stand as a column which supports externally the various elements so as to provide the maximum of accessibility. The other treats the stand as a case which contains the various working parts. The former type is typically illustrated above.

The load limit device is at the upper right, its finger bearing on a collar of the valve stem. When it is in operation, the flyball, its motor, the upper floating lever, the entire dashpot mechanism, and synchronizing motor attachment at the upper left are inoperative.)

[1] Hydraulic Engineer, Allis-Chalmers Mfg. Co. Life Mem. A.S.M.E.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., Dec. 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

grouped in one system and combined with lighting and traction loads, the necessary refinement in control of voltage and frequency more than offset any advantage in diversity factor of load changes, so that regulating requirements were still severe. With more extensive system interconnection, the increase in total system flywheel effect, and the very small load changes resulting from wide diversity of load have altered conditions so that the governor on any individual unit may have a negligible effect on the system. As a result, and for gain in other directions, most of them are run "on the block," that is, with the flyballs inoperative, and as an emergency shutdown means only.

There is at present in this country a total capacity of hydraulic turbines under governor control far in excess of any possible load

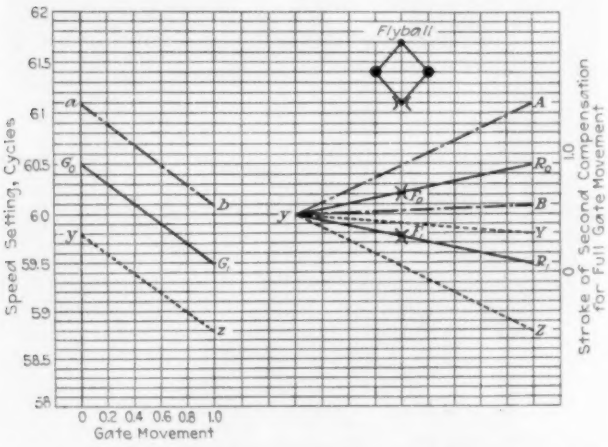

FIG. 2 DIAGRAM OF RELATIONSHIP BETWEEN FREQUENCY, GATE OPENING OR LOAD, THE NO LOAD TO FULL LOAD SPEED RANGE OF A GOVERNOR, AND ITS ADJUSTABILITY THROUGH THE SYNCHRONIZING MOTOR

(For proper division of load between units a normal range G_0 to G_1 is required from no load to full load. This may vary from one to three cycles and the shape of the connecting curve may be varied to effect desired relationships between units. Without altering this range the synchronizing motor is used to shift it on the frequency diagram from some such position as R_0 R_1 to AB or YZ resulting in speed ranges a-b or y-z. Ordinarily, this is done by the operator to correct frequency if he finds it low or high. By this correction full load speed may even be made higher than no load speed as indicated by the location of point b at 60.1 cycles and y at 59.8 cycles.

Control by frequency meter if extended to the full capacity range of the unit results in "flat" regulation—i.e., points y and b and also all intermediate load points are brought to 60 cycles.

Load-limit control blocks the effect of the flyball on the regulating valve V for all speeds below normal in the range F_0F_1 wherever it may be shifted on the frequency scale, but leaves it operative for speeds above normal. Similarly, an "anti" load-limit device[2] has certain utility for limiting the reduction of gate opening at overspeeds so as to enforce participation on other governors.)

changes that require continued speed regulation. About the only duty that the governors now installed have to fulfil is that of emergency shutdown when the load is lost completely through electrical disturbance. Under such circumstances speed regulation no longer exists. This is evident from the fact that even our best governors under such conditions permit the speed to vary 20 or 30 per cent, and that condition is not acceptable with any power system. In other words, when this speed variation exists, it makes no difference to the system what the speed of the unit may be because the unit is no longer connected to the system.

The only condition which has come to the author's attention requiring governors on large modern units is that in which the main load of the plant is through a long transmission line, service through which may be interrupted by some such cause as lightning. If under such conditions a plant, say of 100,000 kw., instantaneously loses 90,000 kw. when a line goes out, but has to hang on to a 10,000-kw. local load, governors may help the situation and be a necessity. The local load is subjected under that condition to perhaps a 20 to 40 per cent speed rise, and probably to a very positive voltage rise, so that even then it may be questionable whether the local load might preferably have been dropped entirely and later picked up without imposing such abnormal voltage or frequency conditions. Such a combination, however, is about the only logical set-up of conditions that might require complete speed governing.

[2] Patent pending, Pfau.

INSTABILITY OF HYDRO PLANTS

Instability of hydro units (steam units also) is becoming a large operating problem. By instability is meant that quality of unit which permits it to fall out of step electrically, thereby losing its load even though tied to the line. Present governors operated

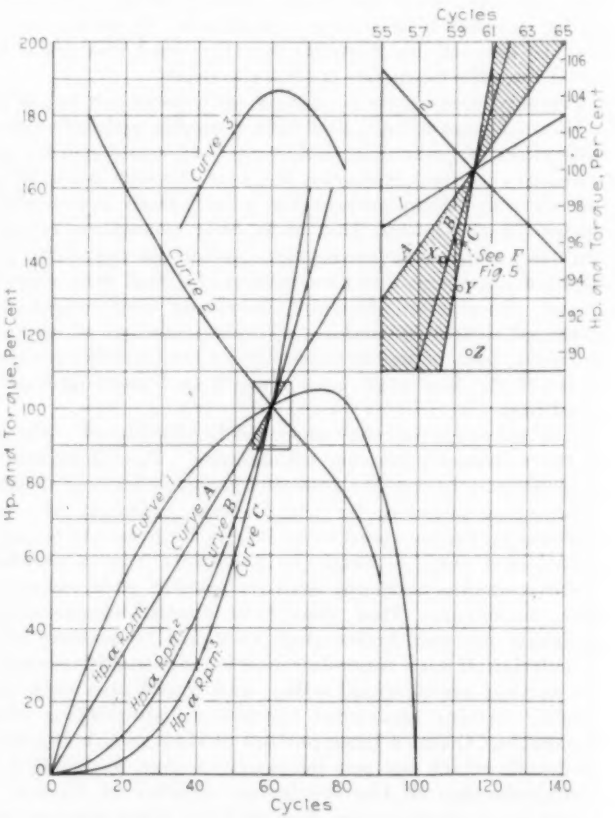

FIG. 3 SOME FEATURES OF SYSTEM CHARACTERISTICS AFFECTING REGULATING OF HYDRO-ELECTRIC UNITS

[Curve 1 shows the speed-capacity relationship of an average water turbine, its runaway speed of 66⅔ per cent being reduced by remaining windage and friction. The corresponding torque is shown in Curve 2, and the efficiency in Curve 3. Curves A, B, and C are load curves varying respectively as the first power, the square, and the cube of the speed. Most loads come within this range. A represents a load such as a sawmill. Curve C is representative of a centrifugal pump or blower load, while B is a composite of the two.

Points X and Y were obtained on systems of about 100,000 kw. capacity by blocking all governors and suddenly opening up the circuit breaker of a unit carrying about 5 per cent of the entire load. The remaining units slow down until the reduction of load at the lower speed brings back a balance between developed and absorbed capacity. System X is moderately self-regulating, while Y is more so. The governing problem on Y would be simpler than on X.

Z was obtained on a system of over 500,000 kw. capacity. All governors could not be blocked, so the end point which for 5 per cent load change is not reached for 15 or 20 sec., has been modified by some active governors opening up.

It is significant in tests of this kind that blocking all governors frequently results in less system frequency variation than with governors active. A reduction from 0.25 cycle to 0.1 cycle has been noted. Three separate systems tested by the author show this general tendency. (Compare B with A, Fig. 5.)

In tests of this kind the 15 to 20 seconds to reach a new stability point is an indication of the flywheel effect or regulating constant of the system. The ultimate speed attained for stability indicates the character of the load assuming all governors blocked. (Fig. 5, F.)]

normally make this situation worse, by increasing the turbine torque at subnormal speeds at a time when it should be reduced. Corrective measures may even be required in the form of a load-reducing coil that takes the control away from the flyballs.

Speed Regulation

Various overall types of regulation are experienced with hydraulic turbines.

1 All turbines are self-regulating to some extent, even without gate movement. The quality is no longer usable because the usual speed range, 20 to 50 per cent from no load to full load, is too great and because the efficiency loss is prohibitive. (See Fig. 3.) Special design can reduce the range, though not to the fractional per cent now desired, but can do but little with the poor economy except through gate closure.

2 A second class of speed regulation is that indicated in the 20 to 40 per cent speed rise guaranteed with instantaneous drop of full load. This results from the excess horsepower while the governor closes the gates upon large rejection of load.

3 A third type is the no load to full load speed change required to permit governors to divide load between units without hunting while on flyball control. This is 2 to 3 per cent. (See Fig. 2.) Range *H* to *L* in curve *C* Fig. 5 is a part of this range.

4 The fourth type, usually called frequency regulation, suppresses the effect of the third class of regulation. (See Fig. 5 *D*.)

The speed change of any rotating mass or system caused by excess or deficiency of generated horsepower is dependent on its flywheel effect and speed. One figure called *regulating constant* expresses its capacity completely.

$$\text{Regulating constant} = \frac{\text{wr.}^2 \times \text{r.p.m.}^2}{\text{hp.}}$$

This constant for the usual hydro-electric unit ranges from about 4,000,000 to 10,000,000. It is simply an index of the capacity of a rotating mass to store foot-pounds of kinetic energy as contrasted to the foot-pounds per second of free energy contained in the excess or deficient horsepower that changes its speed.

indicate that the improvements are frequently more radical than these figures indicate. This gives, roughly, a measure of changing condition as regards regulation of the second class. This speed change is temporary only, as it is corrected by the conventional governor, and by the self-regulating quality of the load. (See curves *A*, *B*, and *C*, Fig. 3.)

The third type of regulation, the speed change from no load to full load, is the permanent after effect of a load change. It is

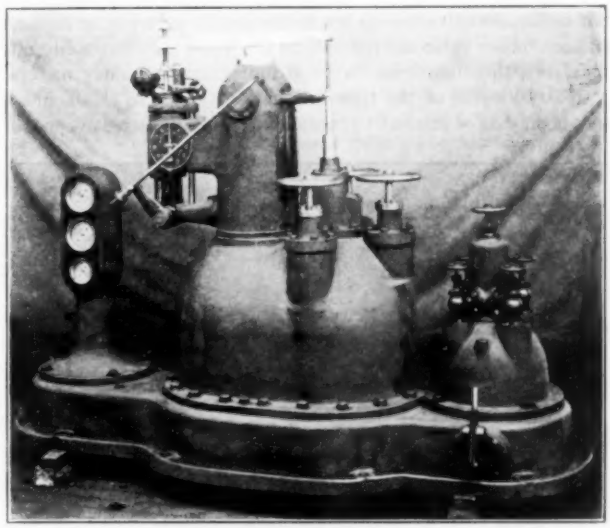

Fig. 4 Governor Stand Typical of Those Used on the 54,000-Hp. Conowingo Units, the 45,000-Hp. Martin Dam Units, and the 70,000-Hp. Niagara Unit, Speed Control Coming From a Shaft Type Flyball as Shown in Fig. 6

(The load limit or block, the rod of which crosses the gate dial, is not motor operated in this particular governor.)

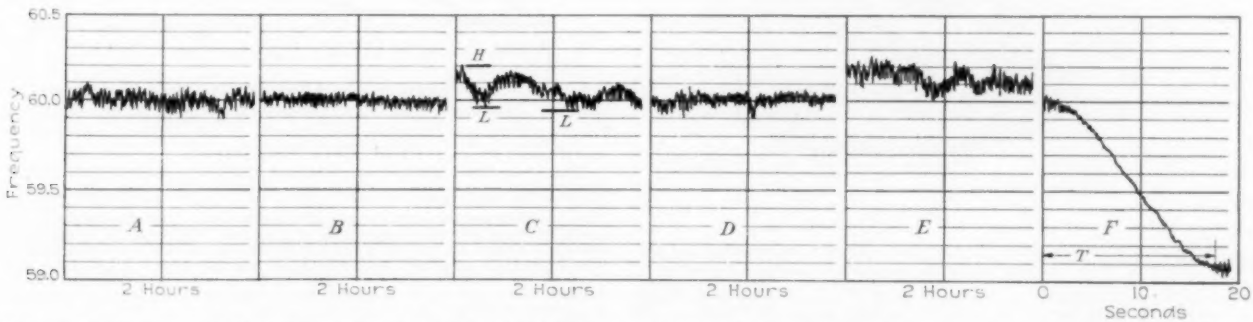

Fig. 5 Representative Frequency Charts Based on Six Systems in Various Sections of the Country. Small Systems Are Below 100,000 Kw. Capacity, Medium Systems Around 100,000 Kw., and Large Systems Around 500,000 Kw. Approximately Two Hours' Time in Each Section

(*A*—Good regulation on medium low-head system and large high-head system, both on governors.
B—Medium system with governors blocked, but no large load swing. Typical of all units set lightly against load limits.
C—Average of two large systems on governor control, but with hand correction of frequency swing resulting from gradual load changes. The usual method for greatest economy of water.
D—Similar system on frequency control. Average of large and medium systems. Wasteful of water if carried out on individual units or plants.
E—Small system without frequency control, but with varying numbers of its governors blocked, up to three-quarters of system load. No significant change evident.
F—Increased time scale indicating the effect of a load increase of 4 per cent of the system load on an average system when all governors are blocked. Frequency control on the load limit would slowly (about 30 sec.) correct the low cycles. The time *T* from opening of circuit breaker is dependent on flywheel effect of the system. The drop in frequency depends on the character of the load.
If load changes are within the operating time of frequency control, the frequency may be held within half a tenth of a cycle, whereas it requires a most excellent governor to hold it within one-tenth cycle without the secondary correction. Quick changes widen the range of both systems as it does that under hand correction. Such changes are not normal on large systems.)

As contrasted to a unit alone on a load like a lighting load and a regulating constant of perhaps 5,000,000, a large system may now have equal or less load changes and a regulating constant of 100,000,000. A load change that would have produced 20 per cent (12 cycles) speed rise with the former, will only produce about 1 per cent (0.6 cycle) with the latter. Actual field results

necessary only to permit units on flyball control to divide the load without trading it between units. (See Fig. 2, range R_1 to R_0 or G_1 to G_0.) Operation of a governor "on the block" or load limit is customary, and under such condition all flyball action and this third type of speed change become inoperative until manual control or excessive load drop may bring them in.

Frequency Control

The fourth type of control is designated as frequency control. In general, governors as now constructed may be considered to be sensitive to speed changes of $^1/_6$ to $^1/_2$ of 1 per cent and to regulate in parallel satisfactorily, with a no-load to full-load speed difference of 2 to 3 per cent. Expressed in cycles, the former requires 0.1 cycle to 0.3 cycle and the latter 1.0 cycle to 2.0 cycles. Refinement of frequency control affects both of these figures, but in a different manner. It affects the former, in that such insensitiveness as lies in the flyball, its drive, or its connections to the valve are reduced to the $^1/_{10}$ of a cycle readily obtainable with commercial forms of indicating frequency meters, or to 0.001 cycle of the time-integration type. In this connection, it may be of interest to compare roughly the sensitiveness of

Fig. 6 Details of Flyball Arranged for Direct Mounting on the Main Shaft of the Unit, but Mounted for Shop Test

(The forked bell-crank lever at upper right transmits the vertical motion of the flyball collar to the governor stand. This type of flyball is extremely powerful. Two types of design exist in this connection. One type utilizes a light flyball, and builds up the force and travel necessary to move the main governor valve by means of an intermediate relay valve, the stroke of the flyball collar not being mechanically connected to the main valve. The alternate design uses a powerful flyball motion which moves a pilot valve directly in the main valve, so that the position of the latter is at all times mechanically determined by the flyball.

The flyball in above view develops over 50 lb. pull for 2 per cent speed change. The motor-driven type of Fig. 2 develops 30 lb. Both are representative of the latter type of design described above.)

various forms of speed indicators. They may be outlined as follows:

Type of device	Approximate Comparative Accuracy: Thousandths of 1 per cent	Fractional cycles (based on 60)
Slave pendulum	1	0.0006
Chronometer	2	0.0012
Time integration method (Warren)	2	0.0012
Electrical frequency meter	20	0.012
Mechanical tachometer	20	0.012
Hydraulic governor insensitiveness	100	0.06
Hydraulic governor no load to full load	2000	1.2

These figures are only roughly comparative. The pendulum may be more accurate than 0.0006 cycle, and the chronometer different than shown, but the former is probably superior, hence its position.

From the valve to the turbine gates, and including insensitiveness of the valve, there is no difference between independent frequency control and regular governor control, but probably less than one-half of ordinary governor insensitiveness is attributable to that portion of the chain of operation. For speed regulation purposes, except of the third type, these general limits may indicate that frequency control, as such, will effect no radical improvement over previous governing equipment through flyballs alone.

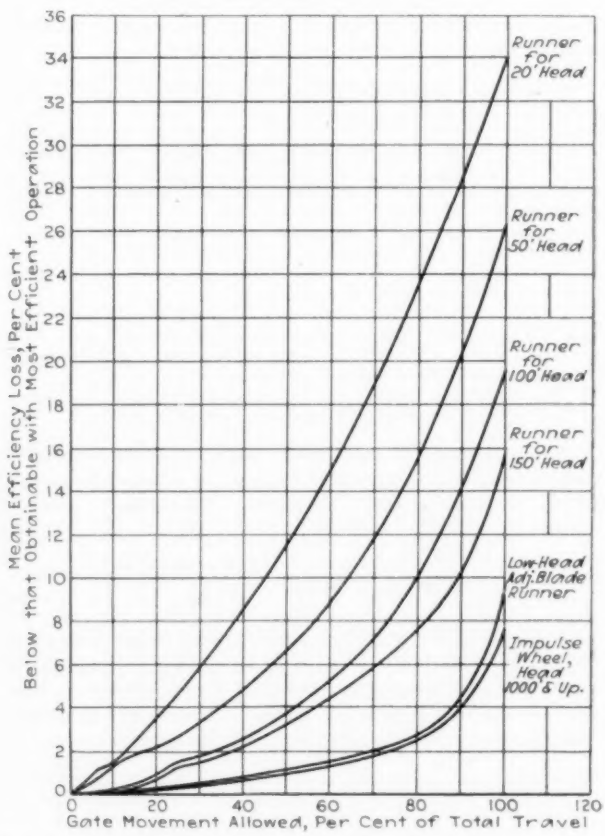

Fig. 7 Curves Showing, for Practically All Types of Hydraulic Turbines, the Percentage of Power Lost by Continuous Flyball Regulation Due to Reduction of Efficiency From That Obtainable

(These may vary slightly for runners of different makes, but the general characteristic is correct and checks out with observed plant performance. Every hydro plant might advantageously have one of these curves drawn from the efficiency curve of its particular type of unit to emphasize the wastage of kilowatt-hours during periods of governor regulation. For example, with such a curve an average plant would suffer a loss of 6.7 per cent in kilowatt-hours if the governors were allowed to regulate over a 50 per cent gate range as, for example, from 50 to 100. This is taken directly from the 50 ft. head curve above. It is simply the reduction in the average ordinate of the efficiency curve over a given range, below the peak ordinate.

Wider ranges of regulation and consequently greater losses are only too frequent. Such losses are further increased if more time is spent at the extreme gate openings of any particular range.)

The third type of regulation, the no-load to full-load difference, becomes of importance when particular apparatus, such as papermill drives and telechron clocks, are considered. The 1.2 to 1.8 cycles variation from no load to full load required completely to shut down a unit operating in parallel is more than is desirable for such modern requirements. For example, a one-cycle maintained variation, applied to a clock system, means about one-half an hour a day gain or loss in all synchronous clocks connected to

that system. This is merely mentioned as an indication of the value of frequency control down to fractions of a cycle.

From a governor standpoint, in order to secure a definite division of load between units operating in parallel or to prevent uncontrolled hunting or switching of load between units, some such a figure as two cycles variation between no-load and full-load speed is practically essential. This necessitates the governor having two ranges, one to permit of operation in parallel and the other to reduce or rather temporarily shift that range so as to enable maintaining constant frequency regardless of load. The quick-acting flyball control (full stroke in about 3 sec.) is then left as now designed, and the frequency control which is relatively slow acting (about 30 sec.), but very much more sensitive, added to it. It does not reduce the flyball range, but shifts that range so that at full load the flyball is centered at the upper end of its operating range, and at no load, centered at the lower end of its operating range. (See Fig. 2*b* to *y*.) The effective length of its range is unchanged so far as dividing load is concerned. The result of this shifting of its range is practically to hold constant speed.

Such a device is easily applied to any governor having a synchronizing motor. Engineers have worked on this as applied to the load-limit device, but as has been demonstrated by the Alabama Power Company, it may be carried out very inexpensively and very effectively, simply by connecting the raising and lowering circuits of the synchronizing motor to the red and green light connections, ordinarily supplied on certain forms of frequency meters. This arrangement does exactly what an operator does if he finds his frequency high or low. He corrects it by shifting the gate position by means of his synchronizing motor which is operated from the push-and-pull switch on the switchboard. If the unit is in operation on load limit, as perhaps 90 per cent of all units now are operated, he should do it by means of his load limit, particularly if that load limit has switchboard control which parallels that of the synchronizing motor. Engineers of the company with which the author is connected prefer the load limit arrangement because that is the only effective one, unless the synchronizing motor connection is operated so far as to take the unit off of the load-limit. This is mentioned as bringing out the fact that frequency control through the synchronizing motor is impossible, or at least is greatly delayed in effectiveness if the unit is on the load-limit device, and units are desirably and usually operated on that basis.

The slowness of the intermittent type of contacts made from the usual mechanically actuated frequency meter permits of the elimination of relay motion just as its elimination is permitted when an operator goes to the board and pulls the synchronizing motor switch to raise or lower frequency.

Kilowatt-Hour Output

The measure of financial performance of a hydro plant is found in the percentage of the kw-hr. inherent in the flow and head that it transforms into kw-hr. on the outgoing line. It should be directly comparable with the simplest bookkeeping of a flour mill, charging the bushels of grain bought and crediting barrels of flour. Hydro plants are initially financed on that sort of an analysis and should be so operated, though requirements of quality of service frequently prevent.

With the tremendous and increasing interconnection of systems, even the largest unit has but small effect on the whole system, so that units may be taken off or put on without noticeable disturbance. Pulling out a 40,000-hp. unit instantaneously makes hardly a noticeable effect on the largest systems, so that taking it off gradually should be entirely feasible. On that basis the maximum kw-hr. production is obtained by running each unit at its best point or with gates completely closed. Run-of-river plants cannot be shut down in case of lack of load without wastage of potential kw-hr., but that situation is rapidly being corrected by the development of offpeak loads exemplified by the installation of "pumpers," or hydraulic storage batteries. Plants which have some storage even though it be but daily or hourly should be the regulating plants, doing such regulation by starting and stopping units, all other plants to regulate very slightly, if at all. Governors designed to enforce such a regime would have an automatic shutdown device operable to close entirely the gates of successive units as their capacity at or just below their best point became excessive, or to open them up again in case of demand. A region of instability would thus be created over such gate ranges as are uneconomical. An upper limit just above the best point would be fixed by the load-limit device which would be backed off in case of excess demand of power and flow in the river capable of meeting it.

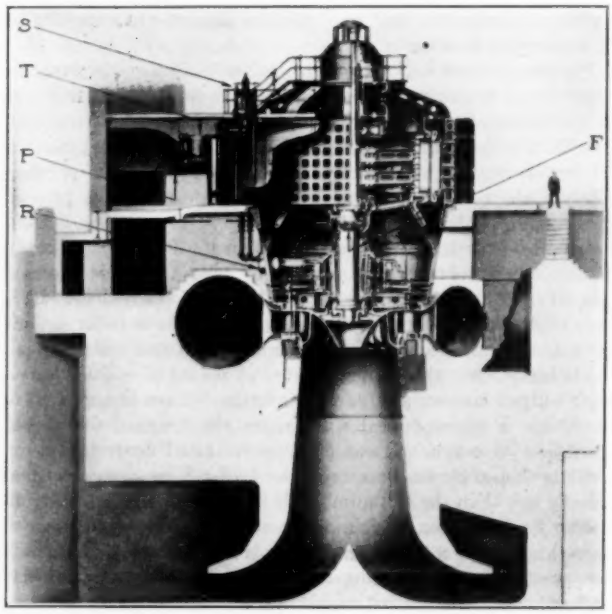

Fig. 8 Modern Large Capacity Unit Illustrating the High Energy Shaft Type Flyball *F*, the Control Stand *S*, the Regulating Cylinders *R*, the Oil Pressure Pump and Tanks, and the Inter-Connecting Piping

(All these elements are present in the conventional modern governor. The cylinders with the oil pumps and tanks are doubtless the most practical speed-reducing and accumulator means available. The other elements are affected more by new requirements of frequency and load control. This unit is installed at Niagara and has carried about 85,000 hp. with a head slightly in excess of 200 ft.)

Governing equipment to meet these conditions should be designed for the following:

1 Opening the gates to start the unit.
2 Controlling the gates to permit the unit to be synchronized with the line.
3 Opening the gates to the point dictated by conditions of flow available, load demand, or as is ideally desirable, to the point of maximum efficiency only.
4 Adjusting the gates to meet any change in conditions.
5 Emergency shutdown of the unit in case of electrical troubles such as instability, loss of load, lightning, etc.
6 Normal shutdown when the unit is no longer desired.

Not a single one of these requirements necessitates the quickness of control typified by the normal two- or three-second governor. In the majority of instances 10 sec. or even 60 sec. operating time is entirely feasible, except for condition (5), and neither that nor requirement (2) demands the use of a flyball

nor does the latter demand the use of quick action. On the contrary, most automatic plants require a deliberate slowing down on the motion as the unit goes through that gate opening which gives approximately synchronous speed. In both this feature of slowing the governor action for synchronizing, in blocking its gates positively by a load-limit device, and in several other ways, the fast governor action around which the most intricate designs are built, are definitely suppressed or eliminated entirely.

Frequency control, except on the basis of continually starting or stopping units, may be quite uneconomical. Mr. McCrea in the *General Electric Review* of June, 1929, illustrates such control down to 0.04 cycle as contrasted to 0.16 cycle on hand adjustment of governor control. From a frequency standpoint the results are gratifying, but to secure them the turbines were apparently operated over such a wide range of gate opening as to reduce the kw-hr. possible from the water used by over 10 per cent. This might mean the loss of the entire net operating profit and illustrates what may happen behind what appears to be a splendid showing.

Frequency control, if carried to the limit, often encountered in large plants, requires operation of one or more units in the plant as synchronous condensers at zero gate opening. This particular condition is the fly in the ointment in load control for maximum kilowatt-hours. The usual operation encountered is that wherein all units but one are blocked with the valve pressed against the load limit by perhaps half a cycle pressure (see Fig. 2), but with one or more units operating on the flyball to take the load swings in so far as they are able by reason of their kilowatt capacity. This is done because it is easy and convenient, but is basically wrong. Generally speaking, all of the units in a plant should be operated at equal gate openings if the units are identical. Technically, they should be operated at points of equal slope on their output curves, plotted on discharge. Even this system of operation is uneconomical when units are designed for proper operation as a synchronous condenser. Load control between units is then difficult, because if the load can be carried on materially less than the full number, it is more economical when dividing load between such a series of units to operate some of them at zero gate opening. This is true if the guide vanes are equipped with special sealing devices, and if the units are properly and automatically vented, simple draft-tube venting not sufficing for high-head units with specific speeds below about 50. This condition introduces some complication in frequency control, just as it does in load control, but is a complication that must be met when kilowatt-hours are the vital consideration. Unfortunately, considerations of load dispatching, convenience in operation, availability of market, and similar considerations, only too frequently preclude the operation of units for the maximum number of kilowatt-hours. It is not generally realized that this condition exists, nor is the remedy usually appreciated, except as a result of analysis of those characteristics of a hydro unit which seldom are written into a contract or shown on the guarantee curve for that unit.

Discussion

ARNOLD PFAU.[3] The paper is an able and timely contribution to the study of a subject which is undergoing radical and basic changes. The fact that we must deal with new requirements brought about by the merger of power systems into one large complex has set problems before us the proper solution of which will require radical changes in the governing means of these various prime movers.

[3] Consulting Engineer, Allis-Chalmers Mfg. Co., Milwaukee, Wis. Mem. A.S.M.E.

What we need in order to meet the new requirements of speed control of large systems may be crudely expressed in the words, "A governor which wakes up sooner, but does not have to get so busy to catch up with its task." To better illustrate this,

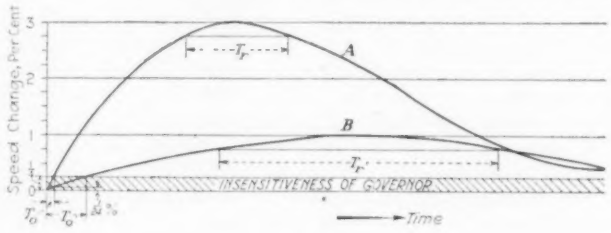

FIG. 9

let us consider two speed-change curves A and B, Fig. 9.

Curve A represents the speed rise in a small power system of, say, 20,000 kw. caused by a load rejection of 10,000 kw., or 50 per cent of its load. This speed rise may be 3 per cent.

Assume an insensitiveness of the governor of $^1/_4$ per cent from the time of the beginning of the load rejection until the control means (servomotor operating the guide vanes, etc.) receive their first motion. Here the ratio between insensitiveness and total speed rise is 0.25 to 3, or 1 to 12. The delay at the start is T_o sec. and may be T_r sec. for a reversal of the speed within the $^1/_4$ per cent range of insensitiveness. Assume a flywheel constant $c = \dfrac{WR^2\,(\text{r.p.m.})^2}{\text{hp.}}$ of the system of $c = 10{,}000{,}000$. Thus the momentary relative speed rise is:

$$S = \frac{800{,}000 \cdot \varphi \cdot T}{c}$$

where $\varphi = 0.5$, so that

$$S = \frac{400{,}000}{10{,}000{,}000} \cdot T, \text{ or } 0.04 \cdot T$$

Curve B represents the speed rise in a large system of, say, 1,000,000 kw. caused by a load rejection of 50,000 kw., or 5 per cent of its total load. Here the speed rise may be only 1 per cent, because the flywheel constant of that large system with all its rotating elements of prime movers and industrial driven parts may be 100,000,000, so that

$$S = \frac{800{,}000 \,.\, 0.1}{100{,}000{,}000} \quad T = 0.008 \cdot T$$

If the same kind of governor is used—i.e., with an insensitiveness of $^1/_4$ per cent—then the ratio between insensitiveness and total speed rise is 0.25 to 1, or 1 to 4, or three times as severe as it was with the small system, although a load rejection of only one-tenth (5 per cent as against 50 per cent) in intensity took place. Thus the delay becomes T_o' sec. and T_r' sec., which is also correspondingly more pronounced.

From the diagram (Fig. 9) it is evident that if the delay T_o were to be maintained also for curve B (that is, for the large system) the insensitiveness of the governor would have to be about $^1/_{24}$ per cent instead of $^1/_4$ per cent. In the small system the $^1/_4$ per cent insensitiveness represents, say, one-twelfth of 10,000 kw., or about 835 kw. In the large system it amounts to one-quarter of 50,000 kw., or 12,500 kw., which is fifteen times the former amount. The governor of the large system has "overslept," so to speak, in an amount of about 11,665 kw. It is obvious that this delay cannot be made up, because a correspondingly quicker movement of the control means of the turbine may become prohibitive on account of penstock conditions, etc.

It therefore seems to the writer that the question of sensitiveness is one which should receive the greatest attention, and he cannot but feel that a participation of as many prime movers in the control of the speed of the system will prove to be the most effective solution, provided that—

(1) their governors are highly and equally sensitive
(2) they operate at a moderate rate of gate motion
(3) they are normally limited in their action to within that range of output which still assures a satisfactory efficiency.

S. Logan Kerr.[4] The writer wishes to commend the author for his very clear summary of the present trend in hydraulic-turbine speed regulation. This fact of changing requirements is not as generally appreciated as it should be, although operating engineers of the various power companies have had this fact drawn to their attention through the new requirements in operation due to the extensive interconnections of power systems and their attendant problems.

The very interesting relations shown in Fig. 3 illustrate the self-regulating characteristics of power systems. This is a very interesting graphical representation of the statement which the writer made at a meeting held in Utica, New York, of the Empire State Gas and Electric Association on the general subject of "Automatic Frequency Control." It would be of interest to quote from the minutes of this meeting the writer's remarks since they are particularly pertinent to Mr. Nagler's paper and are not generally available in published form.

"There is an increasing need for constant speed, since many industries depend on constant speed to control their products. In selecting apparatus to control speed or frequency there are three distinct elements which must be considered:

(1) Rate and magnitude of load changes
(2) Capacity available and characteristics of governors
(3) Characteristics of load with respect to speed.

"Electrolytic and electric furnace loads are practically independent of frequency. Centrifugal pumping loads vary as the cube of the speed. Other rotating loads have more or less flywheel effect. Thus a system with a large proportion of electrolytic or electric-furnace load is more difficult to regulate than a system with considerable proportion of rotating or centrifugal pumping load, since the flywheel effect of rotating loads and the speed-power characteristics of centrifugal pumping loads tend to stabilize the system to a considerable extent. The increasing number of interconnections has made it necessary to regulate the frequency within much closer limits than before. Interconnections have also introduced the problem of where to control frequency. Steam units are capable of quicker changes in load than hydraulic units, since there is less inertia in flowing steam, whereas the inertia in flowing water columns is very considerable, particularly in long pipes. On the other hand, extreme variations affect economics, particularly in steam plants. Any governor, operating in parallel with other governors, must have an inherent speed drop from no-load to full-load to insure stable operation with the other units. The purpose of frequency-control equipment is to hold the speed at normal instead of allowing it to follow the inherent speed-drop line. This is accomplished by changing the governor setting or shifting the governor characteristic line in proportion to the increased load."

The author's enthusiasm for the "load limit" feature of a governor is understandable, but the writer cannot look upon this very simple device as the best answer to all operating problems. The load limit is very effective in limiting the maximum output of the unit and in avoiding continuous departures from a desired point of operation. In order to supply the commercial type of service, it is necessary to consider the variations in demand and to follow them rapidly if this elusive thing called constant frequency is to be attained.

The usual operator in the average hydroelectric station must readjust the "pressure" on the load-limit device each time he adjusts the device itself or else the flyballs will not act at the proper increment of speed above normal. This device also has the disadvantage that it prevents the unit from picking up additional load when the demand increases.

Also, the day has not yet come when the conventional governor action can be relegated to the past. Loads do change, and unless they cease to change rapidly, the governor will still be required to control the speed, while the correction of the frequency to normal can be safely left to ultrasensitive but slow-moving automatic devices.

In the last two paragraphs of the paper, the author mentions some of the practical phases of the problem: "Frequency control, except on the basis of continually starting or stopping units, may be quite uneconomical." And in the last paragraph he mentions the problem of load control, outlining its limitations and the difficulties in the way of operating generating stations for the maximum number of kilowatt-hours. The economic division of the load between units, the maintaining of the economic number of units in service, and the use of units as synchronous condensers are all cited as well as "considerations of load dispatching, convenience in operation, availability of market, and similar considerations [all of which] only too frequently preclude the operation of units for the maximum number of kilowatt-hours."

It is just these considerations that go to make up the daily life of the power-system operator. It is just these considerations that must be taken into account if commercial operation is to be conducted with the greatest economy and with the highest standards of service.

The fundamentals of speed regulation must be considered in conjunction with the characteristics of the prime mover, of the load being supplied, and local conditions must also be considered in order to achieve successful operation. One further element which is essential in all of these considerations is that of economy in the broadest interpretation, this being the economy of the system as a whole with respect to the cost of the energy produced.

A new element has entered the field of power generation—namely, the inseparable tie-up between hydraulic engineering, mechanical engineering, and electrical engineering. To consider all phases of the problem of electric-power generation of the most successful type, it is no longer possible for the hydraulic or steam engineer to neglect or ignore the electrical side of the problems, nor is it possible for the electrical engineer to look with disdain upon the work of the hydraulic and mechanical engineers. These elements are so closely interlocked in the final analysis of the problem that it is impossible to omit any single element which may affect the success of the combination.

The fundamentals of speed regulation are becoming more widely understood, the fundamentals of power distribution control are in the process of development, and the fundamentals of economic loading of units and of stations are becoming more widely appreciated. In order to secure the maximum utilization of the generating equipment with the maximum economy, it is necessary to meet certain requirements:

(1) The characteristic of the unit must be determined and the ideal scheme for economic loading established.

(2) The degree of speed regulation possible and the degree

[4] Research Engineer, I. P. Morris & De La Vergne, Inc., Philadelphia, Pa. Assoc-Mem. A.S.M.E.

of speed regulation desirable must be determined from the study of the individual characteristics of the system from the point of view of both the prime mover and the load characteristics, as well as the combination of the two which may be called "the self-regulating characteristics of the system."

(3) With this established, a form of frequency tolerance must be determined based upon these factors and with consideration to the system load demand and the requirements of the customers being supplied with power.

(4) The individual system operating problems must be studied so that their effect on the individual system is not transmitted to broader fields through interconnection.

(5) The schedule of operation must be determined to include consideration of power transfer between systems through interconnections and of the operating schedule required by the various types of generating stations, both steam and hydraulic.

(6) With all of these factors considered, a still further study must be made to determine which of these functions of an ideal schedule can be accomplished by manual means and how many must utilize some other method such as automatic control.

It has been found from actual studies that it is not usually possible to maintain rigid operating schedules when dependence is placed on individual operators. To maintain such a rigid schedule would require the constant attendance of one or more men at the control board to adjust the load between units following any change in the system demand. Load dispatching of the highest order of intelligence would be necessary even to approach the ideal schedule. With automatic control equipment, however, the economic operating schedules can be made an integral part of the functions of the control equipment and various supplementary functions be included to take care of local conditions.

This same principle can be applied to the control of the proper number of units in service and to a combination of plants whereby certain plants can be selected for frequency-control purposes and other plants kept at constant output and the combined efficiency of the entire group of stations maintained at their higher value.

This sounds like a message from "Utopia" or at least some hazy ideal which might be attained in the far-distant future when all ideals will come true. However, this is not the case, as this object has already been accomplished with an installation of automatic control equipment which has been in service for a period of more than a year.

It has been the privilege of the writer to undertake the studies as outlined in this discussion in connection with the Norwood Development of the Carolina Power & Light Company, in which a 60,000-kw. hydroelectric generating station is controlled automatically for a number of different purposes. The equipment which is in operation at this plant controls an economic division of load between units of dissimilar characteristics and maintains constant station output when desired without impairing the availability of the governing equipment for emergency service. At periods when so desired, the control is set to hold constant frequency on the system with the maintenance of the economic load distribution between units simultaneously, and on occasions it controls the distribution of power to various customers through separate tie lines independent of the output on the remaining portion of the station. The control equipment literally performs the functions of an ideal operator at all times and as a result has been termed the "automatic operator."

The writer visited the Norwood plant recently and inspected the equipment. The control has been in commercial operation continuously during one year, and the total outage time was $1\frac{1}{2}$ hours during the year, being due to causes other than the control equipment. There have been no replacements, no repairs, and no renewals required, and in addition the operating efficiency of the station has been maintained at an exceptionally high level. Through the use of the control equipment, operating losses were reduced from approximately 6 to 10 per cent to the order of 2.5 or 3 per cent when the control was first installed and more recently to less than $\frac{1}{2}$ of 1 per cent for appreciable periods.

Analysis shows that the losses which are now experienced are due to only having extra units in service when carrying the system reserve capacity or failing to have the proper units available for operation at the required time. All losses due to improper loading of the units have been completely eliminated.

There are also under construction at present an "automatic operator" for the Waterville Development of the same company, two installations for the Washington Water Power Company (one for the Long Lake Plant and one for the Post Falls Plant), and one installation for the Morony Development of the Montana Power Company.

The field of automatic operation of generating systems is a very large one and has given promise of the most gratifying returns when studied with due consideration to all of the factors involved. The savings made, due to the economic operation of the units and systems, are amazing, and the application of automatic control equipment to a number of the phases of the problem has been shown to be not only possible but highly desirable.

E. E. Woodward.[5] What is the saving in eliminating the governor? Except with very small turbines, power means must be provided to open and close the gates. Electric motors may be used for this purpose, but hydraulic pressure is generally used on account of the ease, exactness, and quickness with which the gates can be adjusted; and because of having stored energy in the pressure tank, the turbine may be stopped or started when electric current is not available.

We must, then, have servomotors, pumps, tanks, piping, valves, restoring rods, manual or remote control of the valves with gate-opening indicator. All we need to make a complete governor is a flyball governor and an anti-racing device. This effects a saving too small to be warranted.

What is the loss in eliminating the governor? Speed regulation is not needed on some relatively small, self-synchronizing, automatic plants which feed into a large system. Here the load may be full or part-gate as determined by the limit stop or by a float at the headwater. Even then the speed governor may occasionally be needed if the plant is called upon to carry a local load if separated from the main system.

All power units must at times be started and connected to the line. If the power is needed badly, as is often the case, any delay will be more or less expensive both to the power company and to the power users.

Back in the time when turbines were to some extent self-regulating, it was not difficult to open the turbine gates to about the right position and have the machine synchronized in a short time. It is different with the modern high-speed runner with draft-tube setting. At no load and with a fixed gate, the speed swing is often as much as 5 or 8 per cent. It would be difficult to estimate what the loss would be if such a unit was without speed regulation. To get it into the line might be possible, but would certainly be difficult, slow, and unsatisfactory. Such a condition is probably the most difficult one that a governor has to meet, but results are being obtained so that synchronizing can be effected with comparative ease and dispatch where it seemed impossible to get into the line without the governor.

[5] Woodward Governor Company, Rockford, Ill.

HENRY E. WARREN.[6] This interesting paper suggests an idea which would have been rank heresy a few years ago and even now may be opposed by the majority of designing engineers. Hydraulic governors for prime movers have been bought for the last thirty years on the basis of performance under conditions rarely met with in practice. Having been deeply involved in the business of designing and building such governors for many years, the writer can fully appreciate the efforts made by the manufacturers, which were actively encouraged by power-plant engineers, constantly to increase the possible speed of motion of the turbine gates. A governor which would open or close the gates in two or three seconds could command a much higher price than another which would require twice that time interval.

It is perfectly obvious, as the author points out, that in actual operation an expensive, quick-acting governor with complicated valve mechanism never has an opportunity to show what it can do. The load and speed changes are so gradual that slow movement of the turbine gates is to be preferred, and the features of sensitiveness and stability are alone important. The real question is how slowly can the turbine gates be closed after circuit breakers have opened without endangering equipment by overspeed and overvoltage. If the generator and turbine are perfectly safe at runaway speed and the electrical apparatus is protected against overvoltage, the writer can see no reason why the gate stroke need be made in less than 10 or 15 seconds. Certainly in system operation this gate speed is adequate to give frequency regulation far beyond that which is obtained or sought today.

The author is undoubtedly correct in pointing out that the sensitiveness of the centrifugal elements of governors now in use is too poor to render much aid in present-day requirements. Accepting his figures of 0.1 and 0.3 cycle as the limit of machine sensitiveness, the examination of frequency records of a large system, such as that of the New England Power Company, discloses that for days at a time there is not a single occasion when the frequency is in error as much as 0.3 of a cycle, and sometimes there are days when there is no error as great as 0.1 of a cycle. Obviously such results could not be secured by governors alone nor does it seem probable that the centrifugal elements played any part in bringing about this degree of speed regulation. It seems quite possible that during these periods of system operation the frequency would have been exactly as good if the centrifugal elements of the governor had been eliminated and they had been used only as convenient gate-setting devices. Of course, the writer does not advocate the elimination of the centrifugal elements, because there are times when by reason of circuit breakers opening or the necessity of running the units independently the speed-control function of the centrifugal elements is necessary; but he agrees with the author that these are secondary functions and the design of the governors may well be modified accordingly.

With regard to automatic frequency regulation, the writer would be inclined to offer an amendment to the author's statement that "frequency control, except on the basis of continually starting and stopping units, may be quite uneconomical." This statement may be true if automatic frequency control is applied only to a single unit on a large system or to a very small percentage of the units on a system; but if simultaneous frequency control is applied to a large number of units on the same system, so as to control all of them together in proportion to their output, especially where those controlled units are in storage plants, automatic frequency control may be as economical as hand control.

This statement assumes, however, that in any case the kind and number of units to be operated in various plants will be intelligently planned in accordance with the anticipated load and actual water and steam conditions. The writer feels quite sure that on large systems the comparatively small percentage of fluctuations in load during the greater portion of the day can be taken care of automatically with great precision and without loss of efficiency if from one-third to one-half of the total generating capacity is under simultaneous control; the remaining generating capacity may be running with fixed output.

This is believed to be true because the short-time percentage fluctuations in load on large systems are for the most part less than 10 per cent and generally less than 5 per cent. Therefore, this would involve a range of generator output, if half the capacity was automatically controlled, of from 10 to 20 per cent on the controlled generator. Such a range should be well within the efficient zone of most modern turbines. Therefore, this kind of regulation should not prevent the most efficient use of the water.

The very great advantage of automatic frequency regulation simultaneous at many points on a system is the tendency of such regulation to reduce greatly the fluctuations in the tie-line loads. Obviously regulation at a single point on a system, whether manual or automatic, involves very large energy fluctuations in the tie lines which diverge from that point; because all changes in system energy which may occur at the most distant points must be corrected at the central regulating point, and the increase or decrease in energy must in the beginning be transferred through all the intermediate tie lines to the point where the change in load has occurred. After correct frequency has been restored by increase or decrease in power at the central regulating point, it is then customary to readjust the tie-line loads by supplementary corrections at other stations.

In the case of automatic regulation at many points on a system, a correction for increased or diminished load at any point on the system is divided proportionately among all the automatically regulated units. This means that the change in output of any one unit is only a small fraction of the total correction, so that if the turbines are operating in the region of their most efficient performance they may continue to remain in that region. Since each regulated station is correcting for only a small portion of the total change in load, the increased or diminished power flows to the point where the load change occurs, over many tie lines, and the change in any one tie line is generally very much less than the total amount of the load change. Therefore, less adjusting of the tie-line loads will be necessary where multiple frequency control is in use. In fact, since there is a tendency for load changes to occur successively at different points on the system, the small tie-line variations are likely to be distributed quite widely over the network and to counteract each other.

When major load changes occur, as at seven, twelve, one, and five o'clock, multiple automatic frequency regulation will be able to handle the situation if the output of the controlled units is sufficiently large to give the most economical results at other times. Obviously, however, it will be desirable to add or subtract at such times some of the units which are running on fixed output so that all units on the system may continue to operate with the most efficient output.

Such readjustment of units as may be necessary to bring about this economical performance can be carried on by hand oftentimes according to a schedule prepared in advance. It would not seem worth while to add to the cost and complexity of the equipment by automatic devices merely for the purpose of shifting the output of a generator three or four times a day from its minimum to its maximum value, or vice versa. Undoubtedly there are certain plants which by reason of size or

[6] Warren Telechron Company, Ashland, Mass.

hydraulic conditions should not be equipped with automatic frequency control apparatus.

The solution of the problem of simultaneous automatic frequency control at many points on a system depends principally upon three factors:

(1) The ability to measure frequency with a degree of absolute precision which is very materially higher than the ordinary operating range of the frequency. For example, if its operating range is ± 0.1 of a cycle, the automatic control device should be able to measure the absolute value of the frequency to a precision much better than 0.01 of a cycle; otherwise, the different frequency controllers will not work in unison, and there will surely be a tendency to trade power.

(2) The automatic control devices must be so perfectly coordinated that they will not only act in unison, but will also bring about proportional correction. That is to say, if a total increase in load of 10,000 kw. comes on a system and there are five regulated stations, each one of these five stations must increase its output by its proportionate share of the total amount. If the stations were equal in size, each one of them should take on 2000 kw.

(3) Multiple automatic frequency control devices must be reasonably free from a tendency to shift load from one station to another. This requirement will practically be met if controllers are perfect with respect to the other two requirements.

There are several possible ways of providing multiple automatic frequency control which will comply with the foregoing requirements. Perhaps the most obvious method is by the use of interconnecting signal wires or a radio broadcasting system which will transmit controlling impulses from a central frequency-measuring point so as to add or subtract simultaneously proportionate amounts of power at many points on a system. Such an arrangement would be ideal as regards coordination, but the expense of installation might be prohibitive.

The second method is that now in use by certain companies where controllers of the frequency-meter type are so arranged as to be slightly biased by generator output. As a result the small inherent error of these meters is neutralized by the amount of the bias at some point in the generator output. This means that such a controlled unit will gradually assume a definite output value on a system which is running at a fixed frequency value. The position which this unit will assume on such a system may be easily altered by manual adjustment of the amount of bias. Controlled units of this type should be stable and should respond practically in unison on small load fluctuations. They do not tend to maintain a frequency curve that is exactly flat, but rather one which has a slight sloping characteristic.

The third method is by the measurement of errors in the integrated frequency determined over very short time intervals by a very special type of master clock. This method has extremely high precision and tends to maintain a perfectly flat frequency curve. The different units are also effectively coordinated. The tendency to transfer power from one station to another is not entirely eliminated, but is reduced to a very low rate, so that it is believed to be practically unobjectionable.

Any one of these three systems can be operated in parallel with the others, but the type of control which maintains a flat frequency curve will probably tend to do a larger proportion of the work of regulating on large load changes.

In the writer's opinion one or more of these three methods of automatically regulating frequency simultaneously at many points on all large systems will eventually come into general use, and the result will be an improvement in the system efficiency —a very marked reduction in tie-line difficulties and an increase in the size of the network which may be operated satisfactorily.

J. P. Jollyman.[7] The operating experience of the Pacific Gas and Electric Company confirms the author's conclusions. This company's system contains 33 hydro plants, with 77 units of all types and sizes, and 5 steam plants. Interconnections are maintained with several other hydro systems.

Nearly all the hydro units are operated on a block load set by load-limit devices or by hand-controlled needle nozzles. In these plants the governors act on a rise in speed of about 0.5 cycle, and they may be required to govern a section of the system which has become isolated. When conditions are normal, only one hydro plant governs, and frequently only one unit is used.

Several of the smaller plants have been re-equipped for semi-automatic operation. The governors have been replaced with controllers operated by penstock pressure and equipped with a motor-operated load limit. These controllers adjust the gates to the water available and close the gates in the event of overspeed. The units must be restarted manually, because the generators are not suitable for automatic synchronizing. Shutdown on overspeed is accomplished by an overspeed trip operating electrically, backed up by a mechanical overspeed trip.

One plant recently built is equipped for full automatic operation. The turbine controller, in addition to the functions previously mentioned, brings the unit up to synchronous speed after the transmission line to the plant is energized. When synchronizing has been accomplished, the controller adjusts the gates to the water available.

The turbine controllers are simpler than governors for small units and medium or high heads, and are therefore preferable for automatic or semi-automatic plants.

The company is considering the application of automatic frequency control to the system, but has not selected the type to be employed.

Each important plant is furnished with information showing the loads for each unit that give the best overall efficiency. Motoring for synchronous condenser effect is best accomplished with impulse waterwheel units. High-head turbines with close runner clearance cannot be safely operated with the casing drained unless provision is made to admit a small amount of water for cooling the runner.

E. B. Strowger.[8] Since definitions may sometimes clarify the treatment of a subject, the writer wishes to submit the following definition of the word "sensitiveness" as applied to governors before discussing this illuminating paper: Sensitiveness of a governor is the degree of speed change required to cause the turbine gates to move in response to changes in speed on the main unit.

The author's conclusion that, except for the correction of frequency due to the inherent speed drop of governing equipment, frequency control, as such, will effect no radical improvement over previous governing equipment through flyballs alone, is an important one to recognize. In other words, with given load and generator characteristics, the small fluctuations in frequency from the average temporary value will still be of about the same order of magnitude with frequency control equipment as without such equipment. Frequency control substitutes the insensitiveness of the frequency control equipment, which for the time-integration type may be of a very small order of magnitude—say, from 0.01 to 0.001 of a cycle—for the insensitiveness of the flyball element, which probably is of the order of 0.05 to 0.15 cycle. The insensitiveness of that part of the

[7] Hydroelectric and Transmission Engineer, Pacific Gas and Electric Company, San Francisco, Cal.

[8] Assistant Hydraulic Engineer, Niagara Falls Power Company, Niagara Falls, N. Y.

governing equipment from the floating lever to the turbine gates remains in any case. This includes that due to pilot-valve lap and that due to lost motion in the floating-lever connection to the flyball element, if this can vary the floating center of the lever for any given speed. This point is mentioned since in practice there are old governors on systems with which the use of frequency control apparatus has been contemplated. Due to avoiding an outage these governors have not been taken down for repairs, and to obtain good results in the application of frequency control devices a thorough overhauling should probably first be made, especially as regards the elimination of lost motion.

The writer has encountered views on the part of men concerned with the operation of hydroelectric plants which were at variance with these statements and were based solely upon the fact that the frequency control apparatus keeps sending impulses to the synchronizing motor until the position of the pilot valve and therefore of the turbine-gate opening has changed enough to bring the frequency to the desired value. It should be remembered, however, that the pilot valve must be restored to neutral again, which involves the taking up of the existing lost motion in the opposite direction to that of the first corrective action. This may result in a tendency of the frequency to swing within the range as determined by the insensitiveness, as just explained.

The best that can be done, then, by means of frequency control in the direction of decreasing the band on the frequency chart which represents the governor's insensitiveness is to change it from, say, the range of 0.1 to 0.3 cycle to the range of 0.05 to 0.15 cycle, which is little different in order of magnitude. It may therefore be said that the limit of tolerance in sensitiveness is controlled, not necessarily by the sensitiveness of frequency control apparatus, but by the sensitiveness of present hydraulic apparatus. It must be realized, however, in making this statement that small quantities are referred to and that the small departures of the pen on the frequency chart from the temporary average value are not entirely due to insensitiveness of the governing equipment. These momentary variations are also dependent upon:

(1) The momentary amount of load changes on the system and the manner in which these load changes are divided among the regulating units.

(2) The momentary amount of excess or deficiency of input energy to each of these units over or under the demanded output.

(3) The amount of connected Wr^2.

(4) The speed-torque relationship of the load.

These momentary fluctuations are shown on the author's Fig. 5. The excess or deficiency in energy transfer from the penstock to the turbine is manifested by a rise or fall in speed of the rotating parts. If in a given system the units having the shortest penstocks and the largest values of Wr^2 were set with the narrowest regulation in order to take the load swings, then the variation in system frequency would tend to be at a minimum. If, on the other hand, the units with the long penstocks and the smallest values of Wr^2 were set with the narrowest regulation, then the variation in system frequency would tend to be at a maximum.

The speed change caused by a load change on any system is given by the following formula. The plus sign applies to the problem of loads off, the minus sign to that of loads on, and in selecting the value of Wr^2 the load should be taken into consideration as well as the generating equipment.

$$\frac{N_2 - N_1}{N_1} = \sqrt{1 \pm \frac{3{,}229{,}000}{N^2 \times Wr^2} \Sigma\,(\text{hp.} \times \Delta t)} - 1$$

where W = weight of rotating mass in pounds
r = radius of gyration in feet
N_1 = normal value of speed in r.p.m.
N_2 = maximum or minimum speed in r.p.m.
$N_2 - N_1$ = change in speed in r.p.m.
$\frac{N_2 - N_1}{N_1}$ = relative change in speed expressed as a fraction of normal speed.
(hp. $\times$ Δt) = integration of excess or deficiency in horsepower with respect to time.

It will probably be interesting to note that at present the Wr^2 value of the generating equipment and the load of the Buffalo, Niagara & Eastern system is approximately from 500 to 600 million sq. ft-lb. The largest value of Wr^2 in any one generator on the system is 70,030,000. If we consider that this value of, say, 550,000,000 for the Niagara system has increased from about 150,000,000 in 1918, then the speed rise obtaining both in 1918 and at present for an amount of excess energy of 100,000 hp-sec. would be 10 per cent and 3 per cent, respectively. This amount of excess energy would correspond roughly to the dumping of 40,000 hp. in 5 sec. from units running at 100 r.p.m., which units were set with a narrow regulation in order to assume the regulation for the system. These figures substantiate those of the author in regard to changing conditions of regulation which have taken place in the last few years.

Although the small fluctuations in frequency are not affected appreciably by frequency control apparatus, the suppressing of that variation due to the inherent speed drop of the governors may result in a big improvement in frequency service, especially where the manual system is not followed up by the operators with vigilance and where the characteristics of the load are such as to be adverse to self-regulation.

The author gives data showing the possible operating efficiency loss due to uneconomical loading caused by controlling frequency to close limits. The improvement of frequency service beyond the point where it begins to interfere with economical load division is probably unwise provided the service is already within commercially satisfactory limits. In general, economical load distribution should be given first consideration and speed regulation second consideration. Any method of frequency control which, by its application or by the application of supplementary devices, interferes least with the maximum production of energy from a given resource is to be highly commended.

Author's Closure

Mr. Warren's discussion is about as complete a comment on this general subject as could be presented. One or two thoughts occur that may be of interest.

While 0.1 to 0.3 cycle may represent average insensitiveness of existing equipment, it should not be forgotten that the inactive band involved in such figures need not always be used in its full width before present governors come into play. Some governors on any existing group may be at or near the top of the band, so that on an average certain changes may be met with considerable refinement of control. It is only on complete reversals that the entire band becomes effective.

Frequency control within the range mentioned by Mr. Warren as "the efficient zone of most modern turbines" does not involve the kind of error that creeps into the operation of many plants, but, even though it does not, it is still less efficient in the production of kilowatt-hours than operation of any unit at a given point only. Any turbine unit has a maximum point of efficiency which is a point only and not a band. Any operation away from that particular point results in reduction of the kilowatt-hours that could otherwise have been produced. Whether this is a sufficient

reduction to warrant some sacrifice in frequency control is entirely a matter of economy and quality of service, but the fact remains that any regulation whatsoever is accomplished at the sacrifice of kilowatt-hours. Fig. 7 is presented in an effort to picture that penalty of regulation for practically all existing types of turbines.

Mr. Strowger's comment on the Wr^2 value of the Buffalo, Niagara & Eastern System is of special interest. It is a more comprehensive picture of the tremendous increases of flywheel effect that are changing the regulation picture. It could only be some such stabilizing influence that makes it almost impossible to note the effect of dropping off loads as high as 30,000 kilowatts from large systems or, as was actually tried, the sudden increase of a similar amount resulting from cutting off a unit carrying that load.

Mr. Woodward's comments are extremely practical. There is no question whatsoever that a standard governor can be installed about as cheaply as any control mechanism. It is not the cost of equipment, but rather the extent to which that equipment may contribute to improper operation that plays such an increasingly important part in plant operation.

The author would not agree with the inference in the closing paragraph of Mr. Woodward's discussion. High-speed runner units are all too frequently unstable, but the correction of the instability from a hand-control gate to a governor-control gate is not always noteworthy. Frequently the governor action may give accumulative swings that are entirely prohibitive. Frequently the complete blocking of the governor will result in a smaller amplitude of swing or a slower swing than with a governor. This is only at the synchronizing point where extremely high-speed units are difficult to control under certain conditions of length of flume and draft tube that give a water-pendulum time somewhere nearly approaching governor time. It hardly seems possible to anticipate and design for such conditions.

Mr. Kerr's comments as to automatic loading units to the economical point are significant as pointing to the increasing attention that is being paid to operating units at their best gate openings. There is no question but such operation of units that are maintaining a frequency is proper. Regardless, however, of the perfection of such control, any operation other than at the point of best efficiency involves a loss that could be avoided. How much simpler and more productive of kilowatt-hours it would be if every unit on a big system could be operated at only one point. This would simply mean that any unit would be operating at that point or have its gates entirely closed. With systems large enough, the steps between numbers of units would not be reflected in a very considerable change in frequency. Such operation would be ideal from the standpoint of efficient use of water. The moment that intermediate control of units to correct the step-frequency changes becomes imperative, Mr. Kerr's suggestions as to the means for proper division of load between units or proper loading of units becomes the logical solution. It is the feeling of the author, however, that the greater simplicity of hand control under definite operating instructions to run units only at their best point, combined with the increasingly negligible effect of starting and stopping units, presents the most fertile field of increasing the kilowatt-hour output of most existing plants. As interconnection becomes greater, the tendency in the direction of that simplicity can hardly fail to become more pronounced.

Determination of the Actual Theoretical Head of a Centrifugal Pump

By MICHAEL D. AISENSTEIN,[1] OAKLAND, CALIF.

THE purpose of this paper is to show how the theoretical head of a centrifugal pump, as calculated by means of the classical theory, can be made to agree with experience. The study presented is based upon the actual performance of a large number of centrifugal pumps. The following symbols and nomenclature are used (see Fig. 1):

d_1 = diameter at inlet of the impeller in feet
d_2 = diameter at outlet of the impeller in feet
K = coefficient of head loss
c_1 = absolute velocity of water at entrance of impeller, feet per second
c_2 = absolute velocity of water at exit of impeller, feet per second
w_1 = relative velocity of water at inlet of impeller, feet per second
w_2 = relative velocity of water at outlet of impeller, feet per second
v_d = velocity in volute casing
u_1 = peripheral velocity of impeller at inlet, feet per second
u_2 = peripheral velocity of impeller at exit, feet per second
θ = water angle
h = total actual head in feet
H_{th} = imaginary total theoretical head
H = actual total theoretical head
e = efficiency per cent
N_s = specific speed in r.p.m.
N = revolutions per minute
δ = casting angle (vane angle).

The equation of the total theoretical head of a centrifugal pump is given by

$$H_{th} = \frac{u_2 c_{u2} - u_1 c_{u1}}{g} \quad [1]$$

where $c_{u2} = c_2 \cos \theta_2$ and $c_{u1} = c_1 \cos \theta_1$.

The following assumptions are usually made when deriving the fundamental Equation [1]:

1 The liquid is incompressible
2 The liquid is inviscid
3 The liquid is frictionless
4 All passages are filled with liquid
5 The liquid follows the angles of the vanes.

To obtain the actual head it is necessary to subtract the losses from the theoretical head:

$$h = H_{th} - \text{losses} \quad [2]$$

and consequently the hydraulic efficiency is

$$e_h = \frac{h}{H_{th}} \quad [3]$$

The pump efficiency is

$$e = e_h \times e_v \times e_m \quad [4]$$

where e_v is the volumetric efficiency, which is the ratio of the short-circuited liquid past the wearing ring to the total quantity, and e_m is mechanical efficiency, which takes care of the power absorbed by the disk friction, stuffing boxes, and bearings.

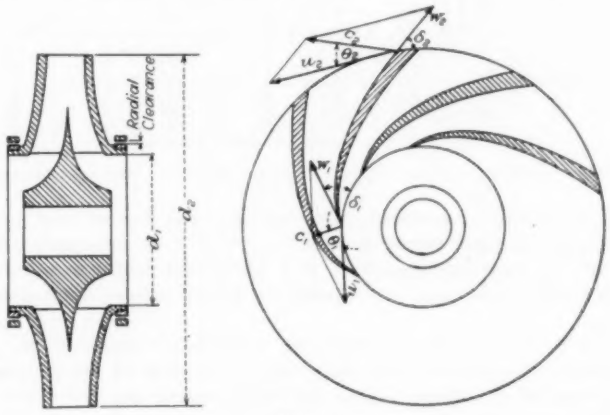

FIG. 1

It is a well-known fact that the hydraulic efficiency when using h from actual test and H_{th} calculated from the physical dimensions of the pump, by means of Equation [1], is very often less than the pump efficiency, which includes the volumetric and mechanical efficiencies.

Many discussions have arisen over this fact, and attempts[2] have been made to discredit the sound fundamental Equation [1] on the ground that it gives too large values of H_{th}.

Since u_2 and u_1 are functions of the outer and inner diameters of the impeller, they are fixed quantities. c_{u1} is small, and the product $u_1 c_{u1}$ has a relatively small effect upon H_{th}, therefore we have to look for an error in the calculations of c_{u2}.

Most of the authors on hydraulics agree that the velocity c_{u2} as calculated from dimensions and angles of the impeller is never obtained, since the assumption that water follows exactly the casting angles does not hold true.

Experiments indicate clearly that the theoretical head for the same outer diameter of an impeller depends upon the number of vanes, the curvature of the vanes, the ratio of the diameter of the impeller eye to the outside diameter of the impeller, the width, and the shape of the blade, and the design of the suction elbow and the discharge casing.

As an illustration see Fig. 2 where are plotted two head-

[1] Chief Engineer, United Iron Works. Jun. A.S.M.E. Previously hydraulic engineer with Byron Jackson Company. Graduated from University of California in 1924. Has made improvements and inventions in connection with centrifugal pumps and has contributed a number of papers to American and European technical press. He received THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS Junior Award for the year 1928.

[2] "Centrifugal-Pump Economics," by A. F. Scherzer. Trans. A.S.M.E., vol. 51 (1929), paper FSP-51-15.

capacity curves from actual tests which show the effect of the number of vanes in the impeller. Both impellers were of the same design, the only difference being that one had 8 vanes and the other 16. Therefore c_{u2} is not a simple function of angles and radii, and a correction factor should be introduced which will modify the value of H.

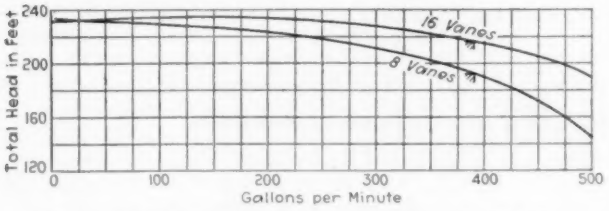

FIG. 2 HEAD-CAPACITY CHARACTERISTICS OF A $2^1/_2$-IN. CENTRIFUGAL PUMP

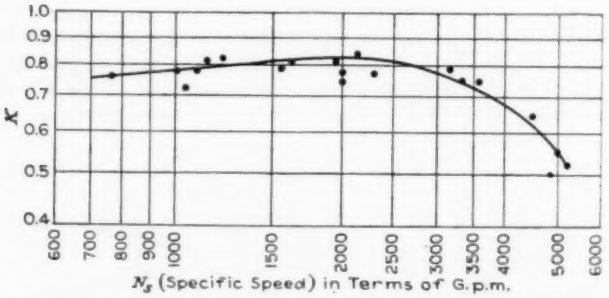

FIG. 3 RATIO $K = c'_{u2}/c_{u2}$ PLOTTED AGAINST SPECIFIC SPEED

As already mentioned, there are so many factors that influence H—and correspondingly c_{u2}—that it is impossible to take up each one separately; and this led the author to search for some term which would embrace all the factors influencing c_{u2}.

Very fortunately we have the expression "specific speed," which possesses the advantage that it involves all the peculiarities of the design of the centrifugal pump and determines the type of impeller.

The "specific speed" (N_s) in terms of gallons per minute is the speed at which a model of a pump when reduced proportionately in all dimensions from the original will deliver one gallon per minute at a head of one foot.

$$N_s = \frac{N\sqrt{\text{g.p.m.}}}{h^{3/4}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [5]$$

Every designer of centrifugal pumps is familiar with the fact that any change whatsoever in design of the impeller results in a change of the specific speed.

For this reason the author determined from actual tests and physical dimensions of a number of pumps the ratio $K = c'_{u2}/c_{u2}$ and plotted this against the corresponding specific speeds. (See Fig. 3.) This chart enables the designer to make a correction for c_{u2} and theoretical head when the head, capacity, and speed—and consequently the specific speed—of a pump are given.

After c'_{u2} is determined, the whole velocity diagram at the discharge of the impeller can be easily calculated.

Analyzing the curve shown in Fig. 3 it is seen that K increases gradually with the specific speed, and after reaching a maximum between $N_s = 1500$ and $N_s = 2800$, drops more abruptly.

At higher specific speeds, say, from 3000 to 5000, the impeller is very pronouncedly of the mixed-flow type, with the ratio of inlet to outlet diameter approaching unity; this results in relatively poor guidance of the liquid and the coefficient K decreases.

On the other hand, as the specific speed decreases the casting angles become smaller and the vanes have a much greater curvature.

Moreover, because of the relatively small angles the number of vanes decreases. This affects the guidance of the liquid and the coefficient K again decreases.

It is worth while mentioning that the highest efficiency is obtained when the specific speed is such that the value of K is a maximum.

This suggests that because of better guidance the losses become smaller and consequently the efficiency of the pump is improved.

Mechanics of Hydraulic-Turbine Pressure Regulation

By ARNOLD PFAU,[1] MILWAUKEE, WIS.

Problems of pressure control or the pressure variations resulting from the action of the governor complicate calculations of hydraulic turbines. This paper describes mechanical means whereby desired field results can be obtained under existing conditions of operation and of pipe-line characteristics. Calculations, formulas, and examples of speed and pressure control take up such points as closing gates, passing through position of static balance of turbine gates, formulas for speed regulation, effect of pressure variations on speed, and calculations of pressure rises in pipe lines.

THE problems of speed and pressure control of hydraulic turbines are closely interlinked. The problem of speed control is simple when no pressure variations are involved, and the practical methods of calculation are sufficiently accurate for commercial application. It is the problem of pressure control, or the pressure variations resulting from the action of the governor, which complicates the calculations.

Many excellent methods of calculation have been published and formulas have been given for use in practice. Most of these calculations, in order to be possible at all, or to avoid very complicated mathematical problems, are based on certain assumptions, or limitations. If one limitation precludes in practice another limitation, also embodied in the calculation, it is impossible to expect a result which is directly applicable in practice. For instance, it is practically impossible to simultaneously meet all three of the following conditions: namely,

1 That the closure of the turbine gates is a straight-line function with respect to time and no cushioning effect is present at the end of the stroke nor "dead time" at the beginning;

2 That the time required to effect a partial stroke of the gates is a direct proportion of the time required for the full stroke. That is, the closure from half-gate to zero is effected in one-half the time required for the closure from full gate to zero, and that a closure from one-quarter of full gate to zero is made in one-quarter of the full gate time and so on; and

3 That the discharge through the orifice and hence the average velocity in the conduit is considered to be a direct linear function of the opening of the orifice, there being no variation in the coefficient of discharge.

This paper is not intended to depreciate the value of present methods of calculation, but merely endeavors to describe practical mechanical means whereby desired field results can be obtained under actual existing conditions of operation and of pipe-line characteristics.

To explain these means properly a brief analysis of the principles of functioning of a servomotor is made, and a few suggestions are added.

Hydraulic-Turbine Governors

Rating. It has become an accepted practice to rate hydraulic-turbine governors, or servomotors, in foot-pounds. This is incomplete in two ways:

1 The time element is omitted, and

2 The maximum force available at any intermediate position of piston stroke is not indicated.

1 *Time Element.* It is evident that a servomotor producing the rated foot-pounds in one second is superior to one requiring 10 seconds or more for a full stroke, as was the case with the mechanical governors of the older kind which produced a rotary moment with one or more complete turns for a full stroke. Furthermore, it seems that there is no precise definition of the term "governor time," for which three different values can be distinguished: namely,

a The time T_s required by the servomotor piston to travel over the full stroke S, such as is generally determined by stop-watch measurement of the seconds, and with control-valve piston raised (or lowered) the full stroke Y. It is evident that under the above conditions the servomotor piston travels at its maximum speed, so that T_s is the shortest period obtainable.

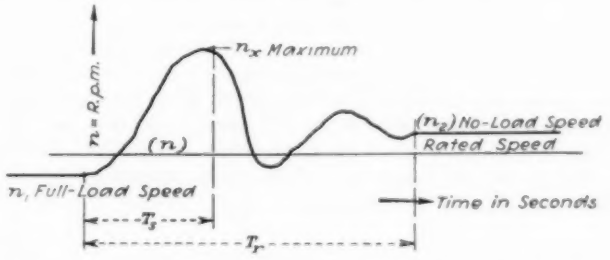

Fig. 1 Curve of Turbine Speed n as a Function of Time (Imperfect governor action because of oscillation.)

b The time T required from the beginning of the load change ΔN until the servomotor piston has completed its full stroke S. This period is longer than T_s because it includes the dead time of the flyballs (t_o, as explained later), and due to the action of the relay or restoring mechanism it does not permit of constant maximum valve lift Y, consequently the servomotor piston does not move at its maximum speed.

c The time T_r required from the beginning of the load change ΔN until the new constant speed has been attained in accordance with the new load. This period is the longest of the three, because it includes that additional time over T which is occupied by possible speed waves Fig. 1 (hunting with decreasing amplitudes), or by a gradual reduction, Fig. 2, from a larger speed variation to a finer adjustment, as obtains with a so-called second-relay compensating dashpot.

Maximum Force. A governor may be capable of producing the total foot-pounds required for a full-stroke operation, yet it may prove unfit if it lacks that maximum force necessary at an intermediate point of stroke to overcome the resistance of the turbine operating mechanism.

It is proposed here to rate a governor in foot-pounds per second, implicitly, giving the three values of

1 Stroke of servomotor piston, in feet

2 Pounds pressure upon the servomotor piston, and

3 Time in seconds for completing one full piston stroke.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The symbol for this correct rating may be written.

$$E = \text{ft-lb. per sec.} = SP/T_s \quad \ldots\ldots [1]$$

In order to properly discuss the essential features of a servomotor (or fluid pressure) governor, a brief analysis of its fundamental performance may be given, by referring to Fig. 3.

The essential elements of the governor proper are:

1 The flyballs, or any other speed-responsive means.

2 The control valve admitting fluid under pressure to one side of the servomotor piston and draining the fluid from the opposite side.

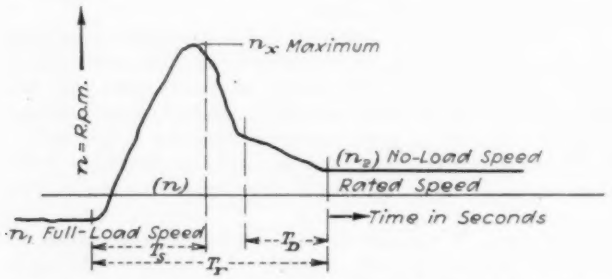

FIG. 2 CURVE OF TURBINE SPEED n AS FUNCTION OF TIME (Satisfactory governor action because of no oscillation. T_D is time of corrective action of secondary relay compensation.)

3 The relay or restoring mechanism which restores the control-valve piston F, to mid, or dead-beat position, so that the gate motion of the turbine again comes to a stop.

Space does not permit dealing with all the essential elements of the governor, but only with the control valve proper and the servomotor in relation to the control of the flow of water through the turbine, as affecting the speed of the unit and the pressure in the pipe line, if one is employed.

The process of regulation will be easily understood by referring to Fig. 3. Any speed rise

$$\Delta n = n_x - n_1 \quad \ldots\ldots [2]$$

causes the speed-responsive means to lift the floating lever ABC at joint B. Since the servomotor is in in its mid- or dead-beat position, C is temporarily a fixed point, so that the lever end A raises the control valve piston F, thereby admitting oil pressure p_a through port I, to the closing side of the servomotor piston E, at the same time allowing the oil from the opposite side of the piston to drain through port II. The servomotor piston then starts to move in the direction which closes the turbine gates, at the same time raising lever end C independently of any change of position of pivot B, so that end A is lowered and the control-valve piston finally restored to the mid- or dead-beat position in which both ports are closed, thereby completing what may be termed the initial and essential cycle of servomotor motion.

It is evident that if the servomotor can move sufficiently fast so that C will be raised almost immediately after B is raised, this will allow end A and along with it the control-valve piston to practically maintain its mid-position. In other words, the servomotor follows the motion of the speed-responsive means without delay, so that no over-regulation takes place; that is, there is no hunting or wave in the speed curve during the load change

$$\Delta N = N_x - N_1 \quad \ldots\ldots [3]$$

This kind of regulation is termed "aperiodic" (or waveless) regulation.

If, however, due to lack of flywheel effect, to intensity of load change, or to other causes which will be mentioned later, the speed rises so rapidly that the servomotor cannot follow synchronously, the control valve piston will be raised considerably, resulting in over-regulation, which produces one or more waves in the speed curve during, and even after, the period of load change.

The number of speed waves should be reduced to a minimum as this affects particularly the voltage of a hydroelectric unit. Therefore either the servomotor should be able to move the turbine gates as fast as possible in order to attain the aperiodic regulation, or the speed-responsive means should be so designed that it cannot move faster than at a rate which will allow the servomotor to follow synchronously.

A quick motion of servomotor may be permissible with turbine control which does not affect the operating head or pressure. This condition is met with an open-flume turbine setting having moderate velocities in the head and tail races and a short draft tube, or with impulse wheels where the jet is diverted from the buckets so that the flow of water in the pipe line is not affected. Where the control of the flow by the governor causes variations in the operating pressure of the turbine, the time (and the rate, as will be shown later) must be adjusted accordingly.

It is outside the scope of this paper to discuss in detail the means for preventing the flyball collar (at pivot B) from moving faster than the servomotor piston and relay. Briefly stated,

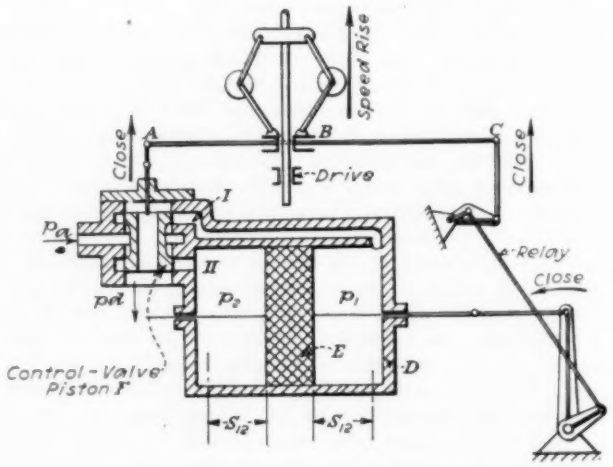

FIG. 3 DIAGRAMMATIC SKETCH OF GOVERNOR

this is accomplished either by employing highly static flyballs (i.e., having a large difference in speed between end positions of flyball stroke) with a so-called flexible relay or double compensation to bring about finally a closer range of speeds between no load and full load, or by using less static flyballs and a compensating device (counter dashpot) which forcibly retards the motion of the flyball collar B temporarily during the process of initial servomotor motion, and which really amounts to nothing more than a temporary increase of the static condition of the flyballs as in the first case. The principal mechanical difference or disadvantage is that the pivot joints of the flyballs and relay are put under a load in the second case, whereas they remain unloaded in the first and thus neither is sensitiveness impaired nor is there any excessive wear of the joints of the relay and floating lever.

GOVERNOR TIME T_s

This is to be understood as the time which the servomotor piston requires to complete a full stroke S, and thus represents

the time required for full stroke at a *constant*, average piston speed[2]

$$C = \frac{S}{T} \quad [4]$$

This time T does not furnish any indication as to the so-called rate of servomotor motion or piston speed ds/dt for intermediate portions of the piston stroke S, and which, as will be shown later, seriously enters into the problem of speed and pressure regulation.

The rate of motion of the servomotor piston is fixed by the quantity of fluid delivered per second under pressure to one side of the servomotor piston and drained from the opposite side. This may be more explicitly discussed by reference to Fig. 3.

Let S = total servomotor piston stroke, feet
y = lift of control-valve piston d, inches
p_a = fluid pressure available at inlet of control valve
p_d = discharge pressure at control valve
p = $p_a - p_d$ = total available fluid overpressure
p_1 = pressure on closing side of servomotor piston
p_2 = pressure on opening side of servomotor piston
$p_a - p_1 = p_{v1}$ = overpressure in port I
$p_2 - p_d = p_{v2}$ = overpressure in port II
D = diameter of servomotor piston, inches
A = area of servomotor piston, square inches

$$A = \frac{\pi D^2}{4} \quad [5]$$

d = diameter of control-valve piston, inches
a = area of control-valve piston, square inches

$$a = \frac{\pi d^2}{4} \quad [6]$$

f = port area of control valve, square inches

$$f = \pi d y \quad [7]$$

The control-valve piston being cylindrical and the ports I and II being equally closed in mid- or dead-beat position,

$$f_I = f_{II} = f \quad [8]$$

m = coefficient of velocity of the fluid under pressure
q = quantity, in cubic feet per second, of fluid under pressure passing through ports I and II
Q_D = total servomotor-piston displacement, cubic feet

$$Q_D = \frac{\pi D^2 S}{4 \times 144} = \frac{D^2 S}{183.34} \text{ cu. ft.} \quad [9]$$

V_1 = actual velocity at which the fluid under pressure passes through the control-valve port I, feet per sec.
V_2 = actual velocity at which the fluid under pressure passes through control-valve port II, feet per second.

$$q = \frac{Vf}{144} \quad [10]$$

Subscripts x designate values for intermediate servomotor piston strokes S_x.

The conventionally accepted rated energy E in foot-pounds is

$$E = p_a \times A \times S \quad [11]$$

[2] It will be seen later that the actual governor time T_g is the period from the beginning of the full-load change $\Delta N = N$ until the servomotor has completed its full stroke S, and that this time T_g is longer than T.

The effective energy per second at an intermediate position of the servomotor piston is:

$$E_x = \left(p_{1x} - p_{2x}\right) A \frac{dS_x}{dt} = (p_{1x} - p_{2x})\, AC_x \quad [12]$$

The corresponding displacement of fluid under pressure in cubic feet per second is:

$$q_x = \frac{A}{144} \times \frac{dS_x}{dt} = \frac{AC_x}{144} \quad [13]$$

However, the relation

$$C_x = C = \frac{S}{T} \quad [14]$$

obtains only provided the servomotor travels at a constant piston speed C, a condition which never prevails because the resistance offered by the gate mechanism of the turbine is not constant but varies over the entire stroke.

The quantities q_x therefore vary, and

$$Q = \frac{AS}{144} = \int_{t=0}^{t=t_s} q_x dt \quad [15]$$

The value of the displacement q_x can be expressed differently:

$$q_x = \frac{V_x f_x}{144} = \frac{V_x \pi d y_x}{144} \quad [16]$$

$$V_x = m\sqrt{2gh_x} \quad [17]$$

where

$$h_x = \frac{p_a - p_{x1}}{0.434} = \frac{p_{x2} - p_d}{0.434} \quad [18]$$

Since $f_1 = f_2$ and $p_{v1} = p_{v2}$,

$$V_x = \frac{m \times 8.02}{\sqrt{0.434}} \times \sqrt{p_a - p_{x1}} = 12.175\, m \sqrt{p_a - p_{x1}} \quad [19]$$

and

$$q_x = \frac{12.175}{144} \times \pi d \times m \times y_x \times \sqrt{p_a - p_{x1}}$$

$$= 0.2656\, dmy_x \sqrt{p_a - p_{x1}} \quad [20]$$

and since

$$p_a - p_1 = p_2 - p_d = \frac{p_a - p_d - (p_1 - p_2)}{2} \quad [18a]$$

and setting $p_a - p_d = p$, also $p_1 - p_2 = p_z$, so that

$$p_a - p_1 = \frac{p}{2}\left(1 - \frac{p_z}{p}\right) \quad [18b]$$

Equation [20] can be written:

$$q_x = \frac{0.2656}{\sqrt{2}} \times dm \sqrt{p}\; y_x \sqrt{1 - \frac{p_z}{p}} \quad [21]$$

or, regrouped,

$$q_x = \left[0.1878\, dm \sqrt{p}\right] y_x \sqrt{1 - \frac{p_z}{p}} \quad [21a]$$

The values d, m, and p are constant.

The total servomotor displacement in cubic feet is, according to [9],

$$Q_D = \frac{D^2 S}{183.34}$$

and the time T_s for a full stroke S is

$$T_s = \frac{Q_D}{q_x} \quad [22]$$

or

$$T_s = \frac{D^2 S}{183.34 \times 0.1878\, dm \sqrt{p}\, y_s \sqrt{1 - \frac{p_x}{p}}} \quad [23]$$

Regrouping and setting $y' = y/d$,

$$T_s = \left[\left(\frac{D}{d}\right)^2 \frac{S}{m} \frac{0.0290}{\sqrt{p}}\right] \frac{1}{y'} \frac{1}{\sqrt{1 - \frac{p_x}{p}}} \quad [24]$$

The values D, d, s, p, and m are constant for a fixed design and available overpressure of the servomotor, so that

$$T_s = R \frac{1}{y'} \frac{1}{\sqrt{1 - \frac{p_x}{p}}} \quad [24a]$$

Equation [24] contains all the factors involved in connection

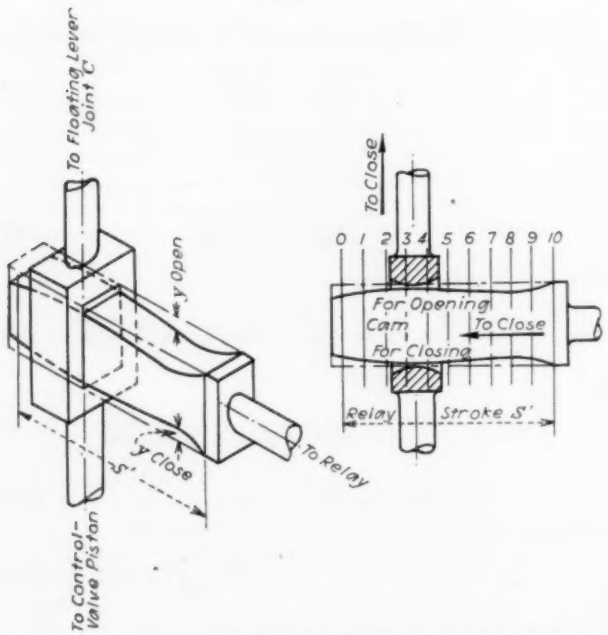

FIG. 4 DIAGRAMMATIC SKETCH OF RATE-LIMITING DEVICE (U. S. Pat.)

with the servomotor characteristic. From these equations the servomotor time T_s is seen to be:

1 Inversely proportional to the valve lift y since $y' = y/d$
2 Inversely proportional to the square root of the available fluid overpressure p
3 Inversely proportional to the *square* of the ratio d/D of the control-valve piston and servomotor piston
4 Inversely proportional to the square root of the ratio of actual overpressure p_x on the servomotor piston (due to resistance from the turbine gates) to the total available fluid pressure p.

These considerations lead to the following conclusions:

Case 1 To obtain largest possible valve lift y, the speed responsive means (flyballs) should be placed *between* the control valve and the relay.

Case 2 Increasing the available fluid pressure p shortens the servomotor time T_s, but only in the one-half power ratio of p.

Case 3 It is important not to use too small a control-valve diameter (d). Reducing this 50 per cent or else increasing the servomotor piston diameter D 100 per cent will increase the servomotor time T_s fourfold.

Case 4 Since p_x represents the overpressure ($p_1 - p_2$) on the servomotor piston necessary for overcoming the resistance of the turbine gates, it is evident that p_x will be <0 if the resistance acts in the direction of the respective servomotor piston motion (for instance, tendency to close gates when closing) and the value p_x/p becomes negative; thus $1/\sqrt{1 + p_x/p}$ shortens the servomotor time T_s.

For a fixed design R, Equation [24a] enables a direct comparison of servomotor time to be made for various intermediate gate positions. Let

$$\left.\begin{aligned} T_{sx1} &= R \frac{1}{y_1} \times \frac{1}{\sqrt{1 - \frac{p_{x1}}{p}}} \\ \text{and} \quad T_{sx2} &= R \frac{1}{y_2} \frac{1}{\sqrt{1 - \frac{p_{x2}}{p}}} \end{aligned}\right\} \quad [24b]$$

then

$$\frac{T_{sx_1}}{T_{sx2}} = \frac{y_2}{y_1} \sqrt{\frac{1 - p_{x2}/p}{1 - p_{x1}/p}} \quad [25]$$

For a constant valve lift $y_2 = y_1$,

$$\frac{T_{sx1}}{T_{sx2}} = \sqrt{\frac{1 - \frac{p_{x2}}{p}}{1 - \frac{p_{x1}}{p}}} \quad [25a]$$

or the servomotor times are in simple relation with their respective ratios of overpressure on the piston to available fluid pressure.

For a constant resistance on the turbine gates the value under the square-root sign is constant, and

$$\frac{T_{sx1}}{T_{sx2}} = \frac{y_2}{y_1} \times \text{constant} \quad [25b]$$

so that the servomotor times are inversely proportional to the respective valve lifts y_2 and y_1. This equation and the general Equation [24a] indicate *that for a design once selected any desired servomotor time T_s can be obtained by properly varying the valve lift "y."*

Since S represents the rate of servomotor piston speed, or the travel T_s per second,

$$\frac{S}{T_s} = \left[\left(\frac{d}{D}\right)^2 \frac{m\sqrt{p}}{0.02093}\right] y' \sqrt{1 - \frac{p_x}{p}} \quad [26]$$

or for a fixed design and fixed value of p,

$$\frac{S}{T_s} = R' y' \sqrt{1 - \frac{p_x}{p}} \quad [27]$$

indicating that by varying the valve lift "y," any desired rate of speed "S/T" of servomotor piston can be obtained; thus,

$$\frac{S}{T_{sx}} = R' y_x' \sqrt{1 - \frac{p_x}{p}} \quad [27a]$$

which applies to any gate position "x."

This can be most conveniently accomplished by a device (rate-limiting device, U. S. Patent No. 1,685,749, granted in 1928) which limits in either direction the stroke of the control-valve piston individually for any intermediate position of servomotor piston. In its simplest form (Fig. 4) it is a cam, operated in synchronism with the servomotor piston. The cam slides through a slot provided in the valve stem, and the surface above and below the cam can be properly determined in the field so as to obtain those valve piston lifts which are required for a desired rate of motion of the servomotor piston.

With such a device any desired rate of servomotor piston motion can be obtained; for instance:

1 A constant rate of piston motion, irrespective of the variable resistance on the turbine gates.

2 A rate which produces a constant rate of change of output of turbine, a feature which would simplify the calculation of momentary speed changes due to sudden change of load in open-flume turbines or impulse wheels, when not subject to pressure variations. All of which will be discussed more in detail in later paragraphs.

3 A rate which produces a constant rate of change of turbine discharge, and which is particularly desirable in cases where pipe-line problems are involved. (Direct control of the flow of water, by the adjustment of the guide vanes of a turbine, or the needle of an impulse wheel.)

4 A rate most suitable for automatic remote control of units—for instance, for *quickly* opening the turbine gates to a point which allows the unit to attain normal speed at no load, then slowing down the motion to permit of sufficient time for automatic synchronizing of the unit, then a quick opening of the gates to pick up full load. Also a desired rate for closing the gates to friction-load opening and a subsequent slowing down for avoiding a serious final pressure rise in the pipe line. Application of the rate-limiting device to control the rate of hydraulically operated butterfly valves, gate valves, etc., in a similar manner has also been successfully made in practice.

5 See Appendix No. 1.

For $p_1 - p_2 = 0$,

$$p_a - p_1 = p_2 - p_d = \frac{p_a - p_d}{2} \quad \text{[18c]}$$

In other words, when no resistance is offered by the turbine gates to the servomotor piston, then the entire pressure difference $p_a - p_d$ can be utilized for forcing the oil through the valve ports I and II, so that q becomes a maximum because, according to [19],

$$V_{max} = 12.175\ m \sqrt{\frac{p_a - p_d}{2}} \quad \text{[19a]}$$

Here $E_1 = E/T = 0$, since $E = PS = 0$, notwithstanding the fact that T is a minimum because $q = Q/T$ is a maximum; but because $p_1 - p_2 = 0$, $P = 0$.

Thus the power in foot-pounds per second is zero.

The other extreme $E_1 = 0$ which occurs when all the over pressure $p_a - p_d$ is necessary on the servomotor piston to resist the reaction from the turbine gates, and

$$p_1 - p_2 = p_a - p_d;\ p_a - p_1 = p_2 - p_d = 0$$

thus $q = 0$, which is the condition when the governor is unable to move the gates, so that $E_1 = 0$, because $T = \infty$ and $S = 0$ (no oil flowing), although $P = A(p_1 - p_2)$ is a maximum.

Between these two extremes $E_1 = 0$ there must be a maximum which represents the most efficient working conditions of the servomotor.

$$E_1 = \frac{E}{T} = (p_1 - p_2)\, A \frac{S}{T} = (p_1 - p_2) AC \quad \text{[28]}$$

since

$$A \frac{S}{T} = q = \frac{vf}{144}$$

Thus

$$E_1 = (p_1 - p_2)\ 0.264\ dmy \sqrt{p_a - p_1} \quad \text{[29]}$$

According to Equations [16], [17], and [18],

$$E_1 = 0.2656\ dmy\ (p_1 - p_2) \sqrt{p_a - p_1} \quad \text{[30]}$$

For a fixed design a given fluid, and for a fixed valve lift y, the values d, m, and y are constant; thus:

$$E_1 = C'(p_1 - p_2) \sqrt{p_a - p_1} \quad \text{[31]}$$

The power in foot-pounds per second is a function of the pressure. E_1 is a maximum when

$$p_1 - p_2 = \frac{2(p_a - p_d)}{3} = \frac{2p}{3} \quad \text{[32]}$$

so that[3] $p_a - p_1 = p_2 - p_d = \frac{p_a - p_d}{6} = \frac{p}{6}$

therefore

$$E_{1\,max} = C' \frac{2p}{3} \sqrt{\frac{p}{6}} = C' \times 0.272\ p^{3/2} \quad \text{[33]}$$

or, explicitly,

$$E_{1\,max} = 0.07226\ dmy\ p^{3/2} \quad \text{[34]}$$

Further,

$$\frac{2}{3} p A \frac{S}{T} = 0.072\ dmy\ p^{3/2} \quad \text{[35]}$$

or, since $A = \pi D^2/4$,

$$7.25\ D^2 \frac{S}{T} = dmy \sqrt{p} \quad \text{[36]}$$

This equation comprises all the essential values of the servomotor and its available fluid overpressure, for the most favorable rating as previously defined and for a constant resistance from the turbine gates.

However, when the resistance is variable the size of servomotor as determined from Equation [36] is not the most suitable. Again referring to Equation [25],

$$\frac{T_{ss1}}{T_{ss2}} = \frac{y_2'}{y_1'} \sqrt{\frac{1 - p_{s2}/p}{1 - p_{s1}/p}}$$

it can be seen that variable forces produce a variable ratio of p_s/p. The smaller the servomotor diameter D, the greater will be p_s, consequently the greater will be the variation in the time T_{ss}.

For example, when the resistance overpressure p_s opposes the servomotor motion in one case and assists it in another, then

$$\frac{T_{ss1}}{T_{ss2}} = \frac{y_2'}{y_1'} \sqrt{\frac{1 - p_{s2}/p}{1 + p_{s1}/p}} \quad \text{[25c]}$$

The ratio between the two times is very pronounced. For a servomotor size D as selected from Equation [36], i.e., where $p_s = 2p/3$,

[3] See author's article in *Die Turbine*, vol. 5, no. 21, Aug. 5, 1909.

$$\frac{T_{sx1}}{T_{sx2}} = \frac{y_2'}{y_1'}\sqrt{\frac{1-{}^2/_3}{1+{}^2/_3}} = \frac{y_2'}{y_1'}\sqrt{\frac{3}{3\times 5}} = \frac{y_2'}{y_1'}\times\frac{1}{2.236} \quad \ldots [25d]$$

Therefore, to obtain a constant servomotor time (or rate) the valve lifts y would differ 224 per cent.

A liberally dimensioned servomotor will in this case hold p_x so low that the ratio $\frac{T_{sx1}}{T_{sx2}}$ or $\frac{y_2'}{y_1'}$ will be closer to unity.

Conclusions. From the foregoing analysis it may be concluded that:

1 For widely variable resistance on the servomotor piston it is advisable to select a liberal size for D in order to avoid the pronounced variation of either valve lifts y or servomotor time T_{sx}.

2 The diameter D of the servomotor piston can be made smallest, and yet the largest amount of foot-pounds per second (E_1) obtained when the resistance forces between the turbine gates and servomotor piston are so transformed that they are nearly constant when acting upon the servomotor piston. (Selection of gate mechanism.)

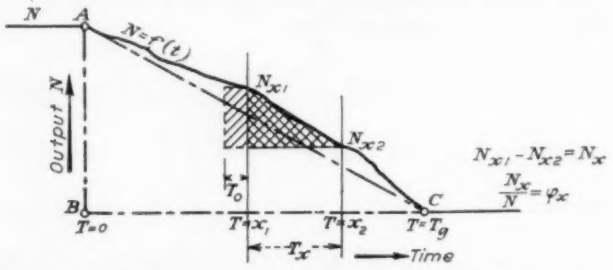

FIG. 5 CURVE SHOWING OUTPUT N DURING A CLOSING PERIOD OF THE SERVOMOTOR AS FUNCTION OF TIME T

Referring again to Equation [24a] and assuming a constant valve lift, we obtain $1/y' = \text{const.}$ Thus

$$T_s = \frac{R'}{\sqrt{1-\frac{p_x}{p}}} \quad \ldots [37]$$

This equation shows the general character of the relation between servomotor time and overpressure on the piston.

In Fig. 8 the times T_s are plotted for values of $R' = 1.7562$. To illustrate the influence produced by a change of either the control-valve diameter d, which does not affect the pressure p_x, or of the servomotor piston diameter D, which affects the pressure p_x, three additional T_s-curves T_{II}, T_{III}, and T_{IV}, are plotted.

T_{II} shows the values of T_s for a control-valve diameter half of that used in curve T_I. The servomotor times T_s shown are fourfold.

T_{III} shows the values of T_s for double the size of both the control-valve and the servomotor piston diameters. These values show the least variations between $p_x/p = \pm{}^2/_3$.

T_{IV} shows the values of T_s when the servomotor piston diameter is doubled, but not that of the control-valve piston. (Here the lower p_x improves the conditions over the most unfavorable ones, represented by Curve T_I, which has the same ratio of servomotor piston to control-valve piston.)

EFFECT ON SPEED AND PRESSURE CONTROL

A speed change of revolving masses is caused either by a surplus or by a shortage of energy, the surplus increasing the speed and the shortage reducing it. Fig. 5 illustrates in dash-dot line a sudden load rejection N. The servomotor closes the turbine gates at a certain rate so that the output of the turbine may be represented by the full line extending from $T = 0$, when the load was suddenly rejected, to $T = T_g$, when the turbine gates are closed [or closed to a point where the output of the turbine has become 0]. The shaded area below the curve $N = f(t)$ [a function of the time] is the surplus energy which accelerates the rotating masses.

If N were a straight line (the rate-limiting device arranged so that the output decreases at a constant rate $dN/dt = \text{const.}$ Case 3, on an earlier page) then we could correctly apply the well-known flywheel formula:

$$n_x^2 - n_1^2 = \frac{1{,}620{,}000\ (N_x - N_1)\ T_x}{WR^2} \quad \ldots [38]$$

where n_x = highest (or lowest) speed in r.p.m. caused by the load rejection (increase)

$\Delta N_x = N_x - N_1$

n_1 = initial speed at time the load change began

N_x = new load in horsepower

N_1 = load before load change

N = maximum rated full load of turbine

$\frac{N_x - N_1}{N}$ = relative load change = $\phi_x N$

T_x = time in seconds which the governor requires from the beginning of the load change $N_x - N_1$ to the completion of the servomotor piston stroke S_x necessary for adjusting the turbine gates to the new position

WR^2 = moment of inertia of revolving masses involved

For full-load change $N_x = N$, $\phi = 1$; $T_x = T_g$, we have:

$$n_x^2 - n_1^2 = \frac{1{,}620{,}000\ N\ T_g}{WR^2} \quad \ldots [39]$$

Equation [38] is the accurate flywheel formula. For moderate speed changes the well-known simplified formula $S_x = \frac{n_x - n_1}{n}$ can be used, namely,

$$S_x = \frac{800{,}000\ N_x T_x}{WR^2 n^2} = \frac{800{,}000\ \phi_x N T_x}{WR^2 n^2} \quad \ldots [40]$$

or, introducing the flywheel constant:

$$C = \frac{WR^2 n^2}{N} \quad \ldots [41]$$

$$S_x = \frac{800{,}000\ \phi_x T_x}{C} \quad \ldots [42]$$

When the rate of change of N is variable the hatched portion of Fig. 5 deviates from the triangular shape ABC, and its value should be figured more accurately.

$$\Delta E = \frac{NT_g}{2} \neq \int_{T=0}^{T=T_g} N dt \quad \ldots [43]$$

or generally,

$$\Delta E = \frac{(N_{x1} - N_{x2})\ (T_{x1} - T_{x2})}{2} \neq \int_{T=x_1}^{T=x_2} N dt \quad \ldots [44]$$

comprising only the double-hatched area of Fig. 5.

To correctly determine this energy change ΔE, it is necessary to know the character of the curve $N = f(t)$.

The governor time, T_g or $T_{x1} - T_{x2}$ in general, is composed of three essential periods:

$$T_g = T_0 + T_1 + T_2$$

(*a*) T_0 is the so-called dead time, or the time required from the beginning of the load change until the insensitiveness of the speed-responsive means is overcome and the point B (Fig. 3) begins to rise (or drop), thereby placing the control-valve piston out of mid or dead-beat position, and causing the servomotor piston to start moving. T_0 therefore depends upon the quality of the speed-responsive means employed (and to a small extent also upon the acuteness of speed change). T_0 = 0.1 to 0.5 sec., depending upon the quality of the governor. It is evident that this dead time T_0 adds to the energy change ΔE.

$$\Delta E_0 = T_0(N_{x1} - N_{x2}) \quad \ldots\ldots\ldots\ldots\ldots\ldots [45]$$

(*b*) T_1, the time from the beginning of the lift (or drop) of the control-valve piston to the point where the maximum lift Y is obtained. During the period $Y = 0$, to Y = maximum, the servomotor piston is accelerated.

(*c*) T_2, the time it takes the servomotor to complete its stroke S_x after the piston has attained maximum speed (rate of motion).

Since T_2 for Y = maximum is not constant (as previously discussed), we can combine T_1 and T_2 and consider them as the base $T = x_1$ to $T = x_2$ of Fig. 5.

We thus have:

$$\Delta E \text{ total} = T_0\left(N_{x1} - N_{x2}\right) + \int_{T=x_1}^{T=x_2} N dt \ldots\ldots [46]$$

and then obtain:

$$550\left\{\left(T_0 N_x + \int_{T=x_1}^{T=x_2} N dt\right)\right\} = \frac{M}{2}\left(V_x^2 - V_1^2\right) = \frac{WR^2}{2g}\left(\frac{\pi}{30}\right)^2 (n_x^2 - n_1^2). \quad [47]$$

or since

$$V = \frac{\pi D n}{60},$$

$$\frac{1}{N}\left(T_0 N_x + \int_{T=x_1}^{T=x_2} N dt\right) = \frac{1}{550}\left(\frac{\pi}{30}\right)^2 \frac{1}{2g}\frac{WR^2 n^2}{N} \times \left(\frac{n_x^2 - n_1^2}{n^2}\right) \ldots\ldots\ldots\ldots [48]$$

or since $N_x = \phi_x N$, n_1 = about n for close relay setting between no load and full load, and

$$\left(T_0\phi_x + \int_{t=x_1}^{T=x_2} \phi dt\right) = \frac{1}{3{,}232{,}991} C\left[\left(\frac{n_x}{n}\right)^2 - 1\right] \ldots [49]$$

or

$$\frac{3{,}232{,}991}{C}\left(T_0\phi_x + \int_{T=x_1}^{T=x_2} \phi dt\right) + 1 = \left(\frac{n_x}{n}\right)^2 \ldots\ldots [50]$$

n_x/n is the ratio of maximum speed n_x due to load change to the normal speed n. For instance, if

$$\frac{n_x}{n} = 1.25, \text{ the speed rise } 100\,\frac{n_x - n_1}{n} = 25 \text{ per cent.}$$

Thus

$$\frac{n_x}{n} = \sqrt{1 + \frac{3{,}232{,}991}{C}\left(T_0\phi_x + \int_{T=x_1}^{T=x_2} \phi dt\right)} \ldots\ldots [51]$$

This equation reduces to [39], when

$$\phi_x = 1,\ T_0 = 0,\ t_x = T_x,\ n_x = n_2, \text{ and } \int_{T=x_1}^{T=x_2} \phi dt = \frac{T}{2}$$

$$\left(\frac{n_2}{n}\right)^2 - 1 = \frac{3{,}232{,}991}{C}\left(0 + \frac{T}{2}\right)$$

or:

$$\frac{n_2^2 - n_1^2}{n^2} = 1{,}616{,}500\,\frac{T}{C} \text{ or } n_2^2 - n_1^2 = \frac{1{,}620{,}000\,NT}{WR^2}$$

From [51] we note at once that the value

$$3{,}232{,}991\,\frac{\left(T_0\phi_x + \int_{T=x_1}^{T=x_2} \phi dt\right)}{C}$$

is approximately the square of the actual relative speed change $\frac{n_{x1} - n_{x2}}{n}$.

The value $T_0\phi_x$ in [51] is independent of the action of the servomotor, namely, $0.1\phi_x$ to $0.5\phi_x$.

The value $\int_{T=x_1}^{T=x_2} \phi dt$ therefore characterizes the process of regulation.

Example. ϕ_x = 0.5 load rejection; T_0 = 0.2; C = 5,000,000 $\int_{T=x_1}^{T=x_2} \phi dt = \frac{0.5 \times 2}{2} = 0.5$ because assumed T_x = 2 sec., or constant rate of change of N.

Thus:

$$\frac{n_x}{n} = \sqrt{1 + \frac{3{,}232{,}991}{C}\left(T_0\phi + \int_{T=x_1}^{T=x_2} \phi dt\right)} = \sqrt{1 + \frac{3{,}232{,}991}{5{,}000{,}000}(0.1 + 0.5)}$$

$$\frac{n_x}{n} = \sqrt{1 + \frac{3{,}232{,}991 \times 0.6}{5{,}000{,}000}} = \sqrt{1 + 0.387954} = 1.174$$

$$\therefore \text{ speed rise } \frac{\Delta n}{n} = 17.4 \text{ per cent}$$

Illustrative Calculation

The variable resistance of the gates of a turbine reduced to the force P in pounds upon the servomotor piston along the servomotor stroke S may be indicated as shown in Fig. 6.

The total change in force P is 50,000 lb. The stroke S of piston is 1 ft. The gates are balanced (P = 0 at O—here at quarter-stroke from closed position). Assume further that

$p = p_a - p_d$ = 200 lb. per sq. in. oil overpressure
I = overpressure curve for gates in dead-beat position
II = overpressure curve for opening gates, and
III = overpressure curve for closing gates

To hold gates open, P_2 = 20,000 lb.
To hold gates closed, P_1 = 30,000 lb.
To close gates, P_2' = 16,500 lb. at wide-open position
To close gates, P_1' = 34,000 lb. at closed position
To open gates, P_2' = 23,500 lb. at wide-open position
To close gates, P_1' = 26,000 lb. at closed position

Closing Gates. At open position, P_2' = 16,500 lb., and at closed position, P_1' = 34,000 lb. Assume one servomotor cylinder with piston rod projecting through both covers, so that the piston displacement is the same on either side of piston,

$q_{v1} = q_{v2}$. Since generally it is not desired to close the gates at a maximum rate, toward the closed position, $P = 30{,}000$ lb. is taken as the force for figuring the most economical dimensions

$$p_1 - p_2 = 2/3\ p_s = 132 \text{ lb.}$$

$$\text{Piston area } A = \frac{30{,}000}{132} = 227 \text{ sq. in.;}\quad D = 17 \text{ in.}$$

The conventional rating of this servomotor would be

$$E = PS = 227 \times 200 = \mathbf{45{,}400\ ft\text{-}lb.}$$

The actual over pressure to produce $p_2' = 34{,}000$ lb. will therefore be

$$p_1 - p_2 = \frac{34{,}000}{227} = 150 \text{ lb., so that } p_s - p_1 = p_2 - p_4 = 25 \text{ lb.}$$

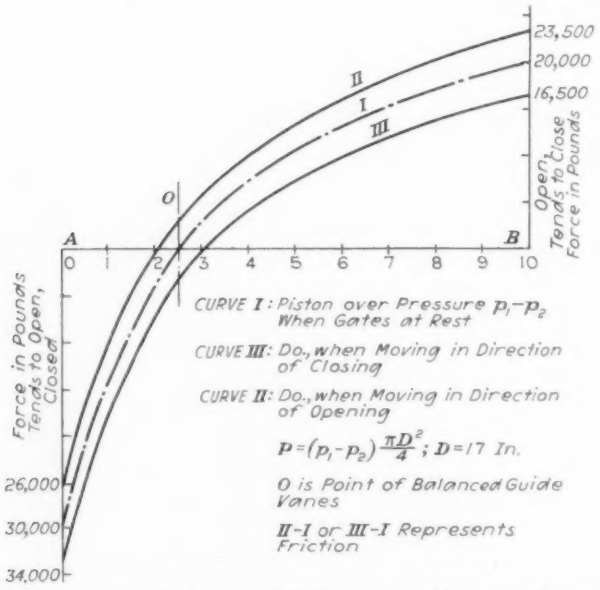

FIG. 6 ASSUMED FORCES ON SERVOMOTOR FOR OPERATING GUIDE VANES

Approaching Closed Turbine Gates. From Equation [20] we obtain the displacement per second in cubic feet.

$$q = 0.2656\ dmy\ \sqrt{p_s - p_1}$$

Assuming $d = 3$ in., $m = 0.45$ for oil, and $y = 0.25$ in.,

$$q = 0.2656 \times 3 \times 0.45 \times 0.25 \sqrt{25} = 0.448 \text{ cu. ft. per sec.}$$

The servomotor cylinder displacement is

$$Q_D = \frac{D^2 S}{183.34} = \frac{289}{183.34} = 1.5763 \text{ cu. ft.}$$

Thus the full-stroke time of the servomotor piston motion is

$$T_s = Q_D/q = C = 1.5763/0.448 = \mathbf{3.51\ sec.}$$

The servomotor piston approaches the end position for closed turbine gates at a rate of speed of 3.51 sec., or from [24],

$$T_s = \left(\frac{D}{d}\right)^2 \frac{S}{m} \frac{0.029}{\sqrt{p}} \frac{1}{y'} \sqrt{\frac{1}{1 - \frac{p_x}{p}}}$$

we obtain:

$$T_s = \left(\frac{17}{3}\right)^2 \frac{1}{0.45} \frac{0.029}{\sqrt{200}} \frac{3}{0.25} \frac{1}{\sqrt{1 - \frac{150}{200}}}$$

$$= 1.750 \times 2 = 3.51 \text{ sec. as before.}$$

Passing Through Position of Static Balance of Turbine Gates (Fig. 6, Point *O*).

$$P_0' = 3000 \text{ lb. for closing gates.}$$

Thus

$$p_1 - p_2 = \frac{P}{A} = \frac{3000}{227} = 13.2 \text{ lb. per sq. in.}$$

and

$$p_s - p_1 = \frac{200 - 13.2}{2} = 93.4 \text{ lb. per sq. in.}$$

Therefore

$$q = 0.2656\ dmy\ \sqrt{p_s - p_1} = 0.2656 \times 3 \times 0.45 \times 0.25 \times \sqrt{93.4} = 0.8662 \text{ cu. ft. per sec.}$$

or

$$T_s = 1.5763/0.8662 = 1.819 \text{ sec.}$$

or again,

$$T_s = 1.756 \sqrt{1 - \frac{13.2}{200}} = \frac{1.756}{0.9664} = 1.819 \text{ sec. as before.}$$

Starting From Wide-Open Gates. Here $P_2' = 16{,}500$ lb. assists in closing the gates. Therefore

$$\frac{16{,}500}{227} = 72.5 \text{ lb. per sq. in.}$$

is the pressure upon the servomotor piston in the closing direction and

$$p_1 - p_2 = -72.5$$

Since $p_1 - p_2 + (p_s - p_1) + (p_2 - p_4) = p_s - p_4$

and $p_s - p_1 = p_2 - p_4$,

$p_1 - p_2 + 2(p_s - p_1) = p_s - p_4$, and we obtain

$$p_s - p_1 = \frac{200 - (-72.5)}{2} = \mathbf{136.25\ lb.\ per\ sq.\ in.}$$

Further,

$$q = 0.2656 \times 2 \times 0.25 \times 0.45 \sqrt{136.34} = 1.047 \text{ cu. ft. per sec.}$$

whence

$$T_s = 1.5763/1.047 = \mathbf{1.50\ sec.}$$

Again,

$$T_s = 1.756 \frac{1}{\sqrt{1 + \frac{72.68}{200}}} = \frac{1.756}{1.167} = \mathbf{1.50\ sec.}\ \text{as before.}$$

The servomotor begins to close from wide-open turbine gates at a rate of 1.50 sec.

Fig. 7 shows the full-stroke servomotor time T_s plotted as a function of the 100 per cent servomotor stroke S.

Vice versa, *if a constant servomotor rate, C,* of say, $T_s = 2\frac{1}{2}$ sec. is to be obtained, the respective valve lifts y_x can be calculated for the three positions in question. Since

$$C = y_x \sqrt{p_s - p}$$

can be calculated and $p_s - p_1$ is a fixed value, we obtain the new required valve lift as follows:

$$\frac{Q_D}{2.5} = q_c = \frac{1.5763}{2.5} = 0.6305 \text{ cu. ft. per sec.} \ldots\ldots [52]$$

$$y_x = y\frac{q_c}{q_x}$$

For Position "A" Near Closed Gates.

$$y_A = 0.25\,\frac{0.6305}{1448} = \mathbf{0.351\ in.}$$

For Balance Point "O."

$$y_0 = 0.25\,\frac{0.6305}{0.866} = \mathbf{0.1819\ in.}$$

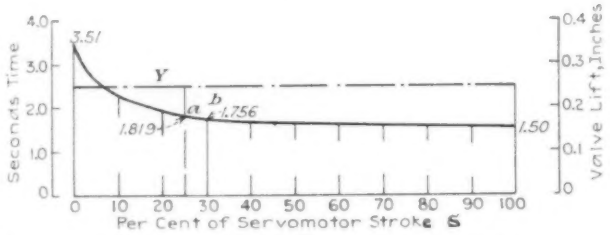

FIG. 7 SERVOMOTOR TIME CURVE AS FUNCTION OF PER CENT OF SERVOMOTOR STROKE

(Based on forces of Fig. 6 for constant valve lift $Y = 0.25$ in. *a*, Point of static balance of gates. *b*, Point of balance when closing.)

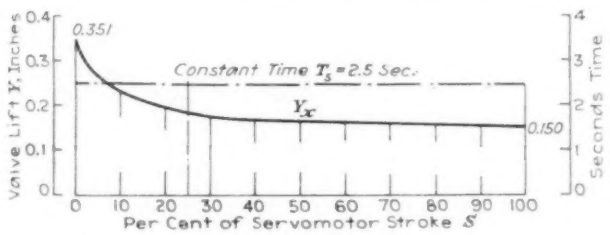

FIG. 7(*a*) CURVE OF VALVE LIFTS Y FOR CONSTANT RATE OF SERVOMOTOR MOTION

(Y_x = variable; $T_x = T_s/10$ = constant. Calculated for $T_s = 0.25$ sec.)

For Position "B" Starting From Open Gates.

$$y_B = 0.25\,\frac{0.6305}{1.047} = \mathbf{0.1502\ in.}$$

as illustrated in Fig. 7(*a*).

In order to obtain a rate of $2^1/_2$ sec. approaching closed gates, the valve lift would have to be increased from 0.25 in. to 0.351 in. This can be very readily accomplished with the rate-limiting device previously described. A constant rate of servomotor piston speed C [2.5 sec., Fig. 7(*a*)] as covered by Case 1 ante does not offer any advantages in regard to speed or pressure control of a turbine, because it results in individual values of $\int_{T=x_1}^{T=x_2} \phi dt$. An adjustment of the rate-limiting device so as to cause valve lifts y which produce a constant rate of change of output ΔN as outlined under Case 2 ante permits of integration of the values

$$\int_{T=x_1}^{T=x_2} \phi_x dt \text{ in Equation [47]}$$

In that case the curve $N = f(t)$ [Fig. 5] becomes a straight line, so that

$$\int_{T=x_1}^{T=x_2} \phi_x dt = \frac{\phi_{x1} - \phi_{x2}}{2}\left(T_{x1} - T_{x2}\right)$$

or for full-load change $= \dfrac{1 \times T_{ss}}{2}$

$T_{ss} < T_s$ because $N = 0$ at friction load N_0 of turbine produced at a stroke S_{rs} of the servomotor piston, and it will take another T_{rs} seconds to fully close the gates.

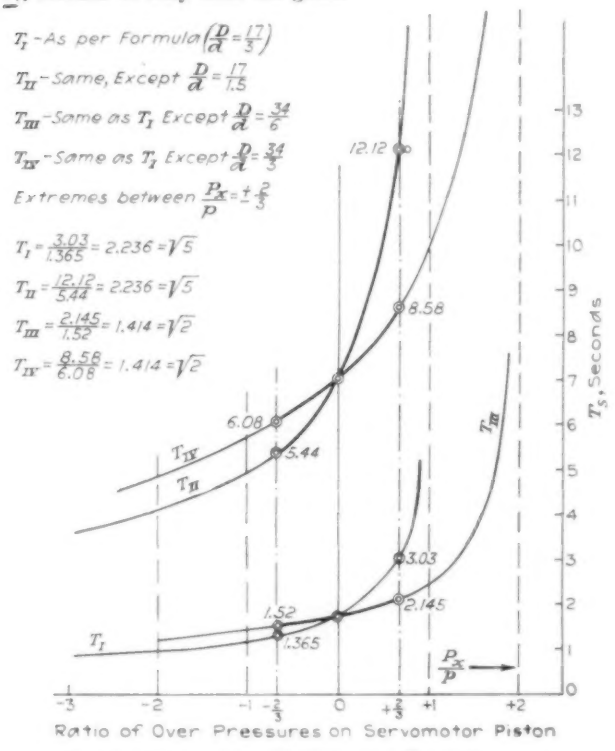

FIG. 8 COMPARISON OF SERVOMOTOR TIMES T_s

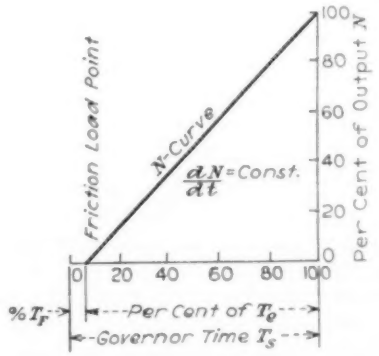

FIG. 9 OUTPUT (N) CURVE AS FUNCTION OF TIME T_s

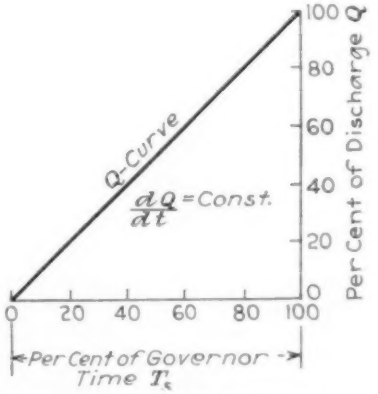

FIG. 10 DISCHARGE (Q) CURVE AS FUNCTION OF TIME T_s

$$\frac{n_x}{n} = \sqrt{1 + \frac{3{,}232{,}991}{C}\left[T_{0\phi_1} + \frac{\phi_1 - \phi_2}{2}(T_1 - T_2)\right]} \quad [53]$$

See also Equation [39] as per Fig. 9.

Where pipe lines are involved, the problem of pressure variations due to load changes becomes important.

An adjustment of the rate-limiting device whereby the servomotor piston travels at a rate which produces a straight-line discharge Q = const. will materially simplify the problem of pressure control. (Fig. 10.)

Here dQ/dt = constant = dv/dt, where v = velocity of water

in pipe line, and the rate of change of velocity remains constant over the whole range of discharge.

In Fig. 11 the output curve N and the efficiency e of the turbine are plotted as functions of the servomotor stroke S. The discharge Q figured from N and e is also plotted. The values of N and e are taken from an actual field test of a 50,000-hp. turbine operating under about 150 ft. head.

In Fig. 12 the full-stroke governor times T_s taken from Fig. 7 are used for obtaining graphically the part-stroke governor times T_x for each 10 per cent ordinate of the servomotor stroke S. The T_x-curve so obtained is again plotted (on a larger scale) in Fig. 13. A constant time rate $T_x' = CT_s$ is the straight line running from $T_s = 1.502$ to 0.

By projecting the 10 per cent points from the T_x' curve horizontally over to the T_x-curve, we obtain in the intersections the new ordinates which, projected to the abscissa line, will give

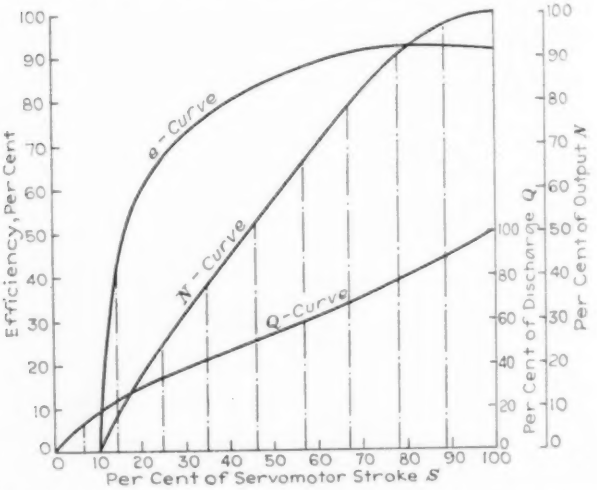

FIG. 11 POWER, EFFICIENCY, AND DISCHARGE CURVES AS FUNCTIONS OF SERVOMOTOR STROKE S

(Taken from actual field tests of a 50,000-hp. turbine at 150 ft. head. Dash-dot ordinates taken from Fig. 13.)

the new increments of per cent servomotor stroke corresponding to the new T_x-curve.

These new abscissa values S_x are plotted in Fig. 11 and furnish the corresponding ordinates in dash-dot lines for obtaining the values N and Q used in Fig. 14 on equal-time elements as abscissas. Thus N and Q are here shown as functions of time. It can be seen that with the exception of the tenth near full load, the N-curve is nearly a straight line, from which we conclude that under the conditions of the time curve, Fig. 7, an N-curve results which permits of almost correct application of the ordinary flywheel formula, if the effect of the dead time T_0 is neglected; or more explicitly, in Equation [51],

$$\int_{T=x_1}^{T=x_2} \phi dt = \frac{\phi_{x2} - \phi_{x1}}{2}\left(T_{x1} - T_{x2}\right)$$

It should be noted that zero load is reached before the servomotor piston attains the closed-gate position. The time to be used in the calculation of speed change is therefore shorter; $T_{s'} < T_s$, as shown in Fig. 14.

The Q-curve as a function of T indicates that the deceleration dv/dt or dQ/dt is greater at the closing end in spite of the fact that the servomotor moves at its slowest rate. The $Q = f(t)$ curve can be used as basis for calculating pressure rises. It will be seen that the pressure rise for changes ΔQ within the first tenth (0–1) of the servomotor stroke is even greater[4] than that caused by a full reduction Q.

The above curves are based on closing rates obtained with a constant valve lift $y = 0.25$ in. Vice versa, we can calculate the corresponding valve lifts for obtaining constant ΔN and ΔQ.

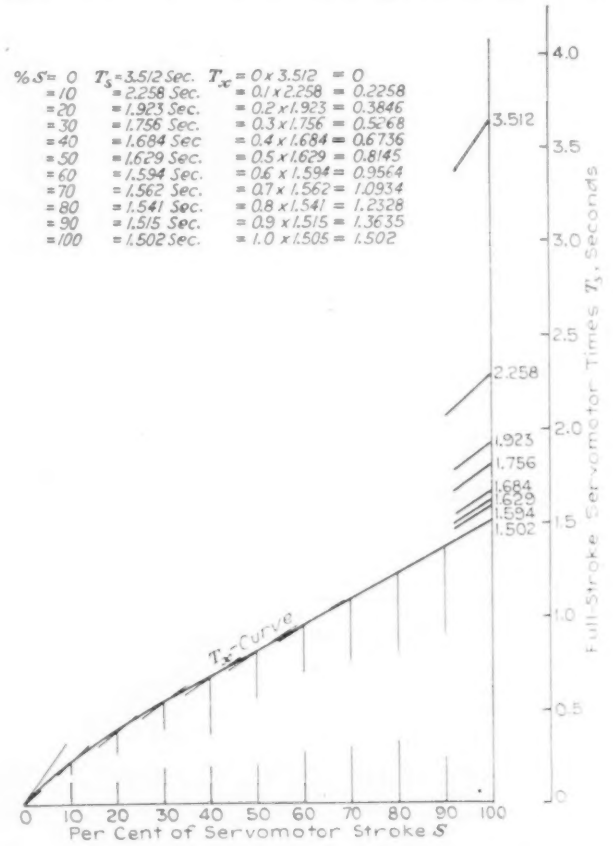

FIG. 12 TIME CURVE T_x (FOR CONSTANT VALVE LIFT $Y = 0.25$ IN.), DERIVED FROM SERVOMOTOR TIMES T_s OF FIG. 7, AS FUNCTION OF PER CENT OF SERVOMOTOR STROKE S

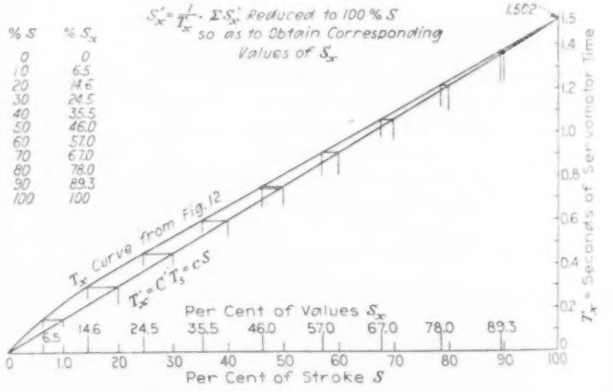

FIG. 13 PER CENT VALUES OF S_x DERIVED FROM T_x-CURVE OF FIG. 12 (ENLARGED SCALE)

In Fig. 14, the abscissas of tenths of N and Q are projected upon the base line, thereby giving those time elements $T/10$ which prevail. These are plotted in Fig. 15. The respective valve lifts are figured from

[4] See "New Aspects of Maximum Pressure Rise in Closed Conduits," by S. Logan Kerr. Trans. A.S.M.E., vol. 51 (1929), no. 6, paper HYD-51-3.

$$y_x = 0.25\frac{T_x'}{T_x} \quad \ldots\ldots\ldots\ldots\ldots\ldots [54]$$

where T_x is $T_s/10$ for the Q-curve and $T_{se}/10$ for the N-curve, and T_x' the respective increment of projection obtained for T_{xN} and T_{xq}, respectively.

The curve marked y_Q shows the valve lifts for a constant change of Q as a function of the time, dQ/dt = const., and the curve marked y_N represents the valve lifts necessary for obtaining constant change of N. The N-curve being almost a straight line requires practically a linear increase of valve lift, slightly increasing because dN/dt is a maximum at the first tenth. It requires a considerable increase toward the wide-open gate position on account of the pronounced deflection of the N-curve. The Q-curve, Fig. 14, indicates a maximum dv/dt at the first tenth and a minimum at the point of inflection about midway. This is evidenced by the upward bulge of the y_Q-curve. It is interesting to note that for the reaction forces P as used from Fig. 6, curve III, a steadily increasing valve lift y would be required for closing constant rate of servomotor piston motion. However, the character of the Q-curve used as the basis in Fig. 11, changes this picture decidedly.

The first practical application of the author's rate-limiting device, Fig. 4, was made in 1924 in connection with the single-jet, horizontal-shaft, double-overhung impulse wheels, rated 2 × 9000 b.hp. under 1260 ft. net head at 300 r.p.m. at the Nakatsugawa Plant No. 1, Japan. The pipe-line conditions (L, V, H,) are within that limit which permits the control of the flow Q, with direct actuation of the needle by the governor. [This being the first impulse-wheel plant where direct control of the flow by the governor was applied and good speed regulation obtained, credit is due the chief engineer of the company and owner of the plant, Mr. Kozo Tada, who accepted the author's conclusions that regulation can be obtained without relief valves or other temporarily water-wasting auxiliaries.]

Without the rate-limiting device the guarantee of 23 per cent maximum pressure rise was fulfilled with a servomotor closing time T_s of $2^3/_4$ sec. for full load thrown off. At smaller load changes, however, pressure rises as high as 33 per cent were observed without the rate-limiting device. The reacting forces on the needle are here the reverse of what was assumed in Fig. 6. The needle has a tendency to open at open position and to close at closed position. Here the time curve (Fig. 8) would be reversed for a constant valve lift y. The two surfaces of the cam (upper for opening needle, lower for closing needle) were experimentally determined at the plant, beginning with very small lifts y so as to hold the pressure variations down, and by increasing them (filing down on the cam surface) until the valve lifts y were such as to hold the permissible pressure variations for any needle opening or output of the units.

Practical Formulas for Speed Regulation

The customary flywheel formula [38], or its more general form [51], does not take into consideration the effect of the runaway of a turbine or hydroelectric unit. With no load taken from the turbine the speed attains a value n_r, which is a function of the output N developed under the operating head H. For full-load runaway n_r may vary between 1.7 n and 2.0 n, depending upon the runner characteristics and the windage and friction losses of the revolving parts of the unit. Since n_r is a limited value irrespective of the load change ΔN, a corresponding correction is applied, namely,

$$S' = \frac{S}{1 + \dfrac{S}{\dfrac{n_r}{n} - 1}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [55]$$

Usually the value n_r is taken as the full-load value. This will result in too great a reduction of S' and can be corrected by introducing an average value

$$\frac{n_{rx1} + n_{rx2}}{2}$$

the runaway speeds corresponding to the turbine gate openings of the output, N_{x1} and N_{x2}, before and after the load change.

The corrective effect of Equation [55] becomes more pronounced as the speed change increases, for $S = \infty$, $S' = n_r$, and $S - S^* = \infty$.

The above formula does not take into consideration the

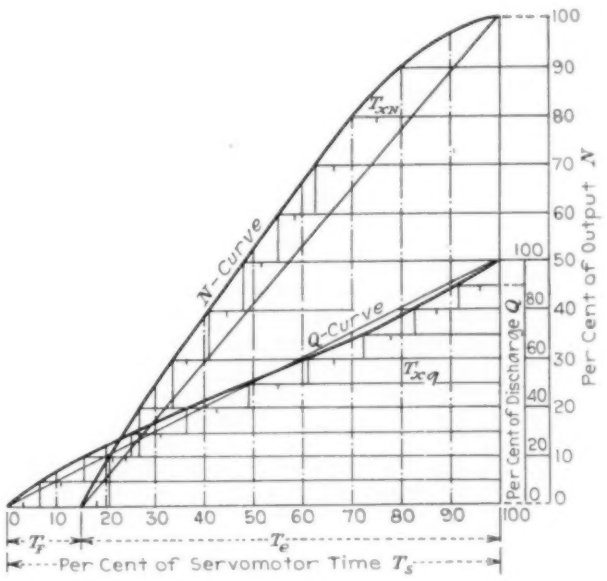

Fig. 14 Power and Discharge Curves N and Q Replotted From Fig. 11 as Functions of Time T_s
(Ordinates taken from dash-dot values of Fig. 11 as obtained from Fig. 13.)

change of efficiency at variable speed and its effect upon N, which, however, for practical purposes of calculation can be neglected.

Pressure Variations and Their Effect on Speed. Any pressure change Δp or change of head ΔH affects the output of a turbine in the ratio of the $^3/_2$ powers of the respective heads, neglecting again the small influence of the variable efficiency if the speed remains constant.

$$\frac{N}{N'} = \left(\frac{H}{H'}\right)^{3/2}$$

If the pressure rise ΔH were instantaneous and remained constant over the entire process of regulation, for practical purposes we could set

$$S^* = S'\left(1 + \frac{\Delta H}{H}\right)^{3/2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [56]$$

The value S^* so obtained exceeds the actual values, if the pressure rise does not prevail over the entire process of regulation. It is therefore safe for practical purposes, although mathematically not sufficiently accurate. With a similar degree of accuracy we can set

$$S_0 = S\left(1 - \frac{\Delta H}{H}\right)^{3/2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [57]$$

as a corrective factor for load increases and resulting pressure decreases. Here the corrective effect due to runaway does not enter into the problem.

Calculations of Pressure Rises in Pipe Lines

The methods of determining $\Delta H/H$ have been liberally discussed in the literature, reference being particularly made here to Mr. S. Logan Kerr's recent paper, "New Aspects of Maximum Pressure Rise in Closed Conduits."[4] This valuable paper, for the first time, points to a critical pressure rise at a point of servomotor position, when a complete closure of the turbine gates is attained by the governor in the time interval $T_r = 2L/a$. In what follows it will be shown that the simple formula cited by Minton Warren in his paper entitled "Penstock and Surge Tank Problems," presented in October, 1914, before the American Society of Civil Engineers, also permits of directly figuring this critical pressure rise.

Warren's general formula is:

$$\frac{\Delta H}{H} = \frac{LV}{gH}\frac{1}{\left(T - \frac{L}{a}\right)} \quad \ldots\ldots\ldots\ldots\ldots\ldots [58]$$

where L = total length of pipe line, ft.
V = full-load velocity of water, in ft. per sec.
g = 32.2 ft. per sec. per sec.
a = velocity of wave, ft. per sec.
H = head, ft.
ΔH = increase in head, ft.
$\frac{\Delta H}{H}$ = relative pressure rise
T_s = servomotor time for full stroke, i.e., full change of velocity V.

For $T = 2L/a$, Warren's formula changes into

$$\frac{\Delta H}{H} = \frac{aV}{gH} \quad \ldots\ldots\ldots\ldots\ldots\ldots [58a]$$

which represents the maximum instantaneous relative pressure rise for full-load rejection in T_s seconds, when $T_s \leqq 2L/a$. This point, however, is not the critical point referred to in Mr. Kerr's paper.

By rewriting Warren's formula, we obtain:

$$\frac{\Delta H_x}{H} = \frac{L V_x}{gH\left(T_x - \frac{L}{a}\right)} \quad \ldots\ldots\ldots\ldots\ldots [58b]$$

as applying to an intermediate gate position at which the water velocity is V_x and the servomotor time T_x.

By setting $V_x = V_m \psi_x$ and $T_x = T_s \varphi_x$ we can write:

$$\frac{\Delta H_x}{H} = \frac{LV_m}{gHT_s}\frac{\psi_x}{\varphi_x}\frac{1}{1 - \frac{L}{a\varphi_x T_s}} \quad \ldots\ldots\ldots\ldots\ldots [59]$$

It will be noted that this value of relative pressure rise $\Delta H_x/H$ is composed of three elements, namely,

(1) $\frac{LV_m}{gHT_s} = A$, a design and operating constant, so to speak. It may be split up further into

$\frac{L}{H}$, ratio of total length of penstock to head,

$\frac{1}{g}$, inversed acceleration,

$\frac{V_m}{T_s}$, which represents the "average" rate of total change of velocity for the total time T_s.

V_m is that average full-load velocity which is obtained as follows:

$V_m = \frac{\Sigma LV}{L}$ and may be termed the average kinetic velocity.

(2) $\frac{\psi_x}{\varphi_x} = \frac{dv}{dt} = \tan\alpha$, the rate of change of velocity of water at the various points of the velocity curve V as a function of the time T_s. Here α represents the angle of the tangent of the velocity-rate curve having φ as abscissa and ψ as ordinate.

(For $\frac{\psi_x}{\varphi_x} = \tan\alpha = 1$ ($\alpha = 45°$), or a straight-line velocity curve, as covered by requirements 1 and 2 outlined at the beginning of this paper and shown also by curve, Fig. 10.)

(3) The value containing the individual time element

$$\frac{1}{1 - \frac{L}{aT_s\varphi_x}} \text{ or } \frac{1}{1 - \frac{B}{\varphi_x}}, \text{ where } B = \frac{L}{aT_s}$$

again a design and operating constant.

It is evident that formula [59] is general and contains as a special case $\psi_x/\varphi_x = 1$, the condition of a straight velocity curve.

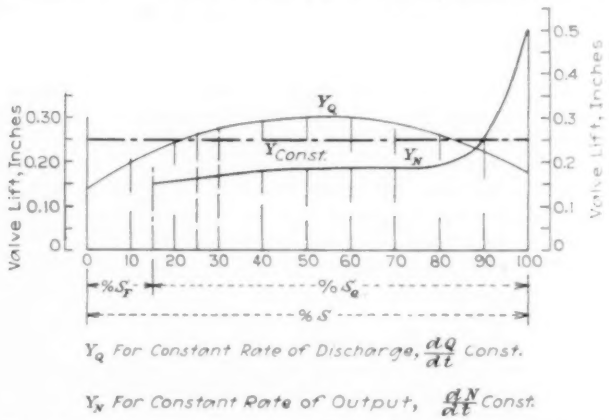

Fig. 15 Valve-Lift Curves as Functions of Per Cent of Servomotor Stroke Figured From Abscissas Taken From Fig. 14

We conclude from the above curve that—

(*a*) The relative pressure rise $\Delta H/H$ is directly proportional to the design and operating constant LV_m/gHT_s.

(*b*) It is directly proportional also to the individual rate of change of velocity $\psi_x/\varphi_x = dv/dt = \tan\alpha$ over the whole range of the curve $V = f(t)$. These rates must average the total value V_m/T_s, therefore an angle $> 45°$ within this range must also cause an angle $< 45°$.

(*c*) It is an inverse function of the individual time element φ_x, viz.:

$$\frac{1}{1 - \frac{B}{\varphi_x}}$$

The critical pressure rise $\Delta H_r/H$ referred to in Mr. Kerr's paper is obtained at once from Warren's general formula by using the author's transformed formula with the restrictions 1 and 2 cited before, i.e., $\psi_x/\varphi_x = 1$; then from [55],

$$\frac{\Delta H}{H} = \frac{LV_m}{gHT_s}\frac{1}{1 - \frac{L}{a\varphi_x T_s}} \quad \ldots\ldots\ldots\ldots [59a]$$

by setting $T_x = \frac{2L}{a}$; or since $T_x = \varphi_x T_s$ or $\varphi_x = \frac{2L}{aT_s}$,

$$\frac{\Delta H_r}{H} = \frac{LV_m}{gHT_s}\frac{1}{1-\frac{LaT_s}{2LaT_s}} = \frac{2LV_m}{gHT_s} \quad \ldots\ldots [60]$$

Fig. 16 shows for a numerical example the percentage relative pressure rises $\Delta H_x/H$ on the basis of a discharge curve Q as shown in Fig. 10 (i.e., $\psi_x/\varphi_x = 1$) as calculated from formulas [59a] and [60] with the following numerical values:

$L = 2000$ ft.
$V_{(max)} = 10$ ft. per sec.
$H = 800$ ft.
$a = 3000$ ft. per sec.

$\frac{2L}{a} = \frac{2 \times 2000}{3000} = 1.33 = T_r$ (critical time)

The values of the percentage pressure rises $\Delta H_x/H$ are plotted for servomotor time T_s of 10, 5, 3, 2, and $1^1/_2$ sec.

For $T_s = 1.333 = 2L/a$ a maximum pressure rise of 116.4 per cent will occur.

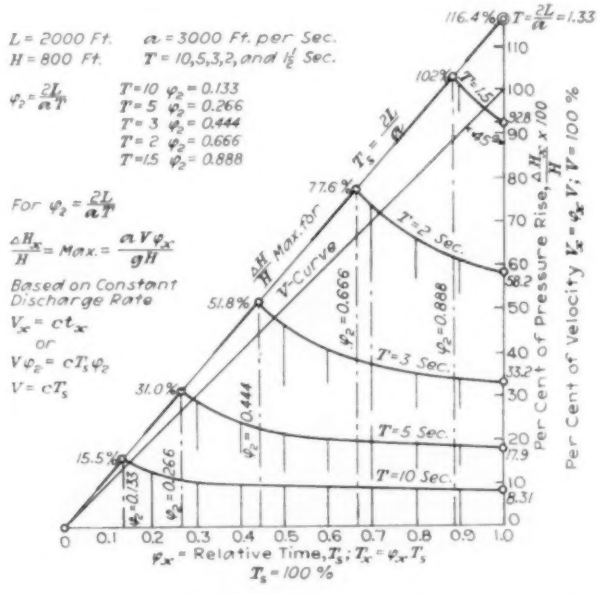

FIG. 16 PRESSURE-RISE CURVES $\Delta H_x/H$ AS FUNCTIONS OF φ_x OR PER CENT OF TIME T_s

For a total time $T_s = 5$ sec., for instance, we obtain, for $\varphi_x = 1$,

$$\frac{\Delta H_x}{H} = \frac{2000 \times 10}{32.2 \times 800 \times 5}\frac{1}{1-\frac{2000}{3000 \times 5 \times 1}} = \mathbf{0.179} \text{ or } 17.9\% \quad \ldots\ldots [60a]$$

The critical pressure rise $\Delta H_r/H$ is obtained by setting $T_x = 2L/a$ or $\varphi_x = 2L/aT_s$, or directly from [60]:

$$\frac{\Delta H_r}{H} = \frac{2LV}{gHT_s} = \frac{2 \times 2000 \times 10}{32.2 \times 800 \times 5} = \frac{10}{32.2} = \mathbf{0.31} \text{ or } 31\% \ldots [60b]$$

If the total governor time T_s were $2L/2$, we should obtain

$$\frac{\Delta H_r}{H} = \frac{2LVa}{gH2L} = \frac{aV}{gH} = \frac{3000 \times 10}{32.2 \times 800} = \mathbf{1.164} \text{ or } 116.4\% \ldots [60c]$$

as before. The maximum pressure rise occurs at $\varphi_x = 1$, $T_s = 2L/a$, in general formula [59].

$$\frac{\Delta H_x}{H} = \frac{LV}{gHT_s}\frac{1}{1-\frac{L}{a\varphi_x T_s}}$$

$$= \frac{2000 \times 10 \times 300}{32.2 \times 800 \times 2 \times 2000}\frac{1}{1-\frac{2000 \times 3000}{3000 \times 2 \times 2000}} \quad \ldots\ldots [59b]$$

which reduces to $\frac{3000 \times 10}{32.2 \times 800}$ as before.

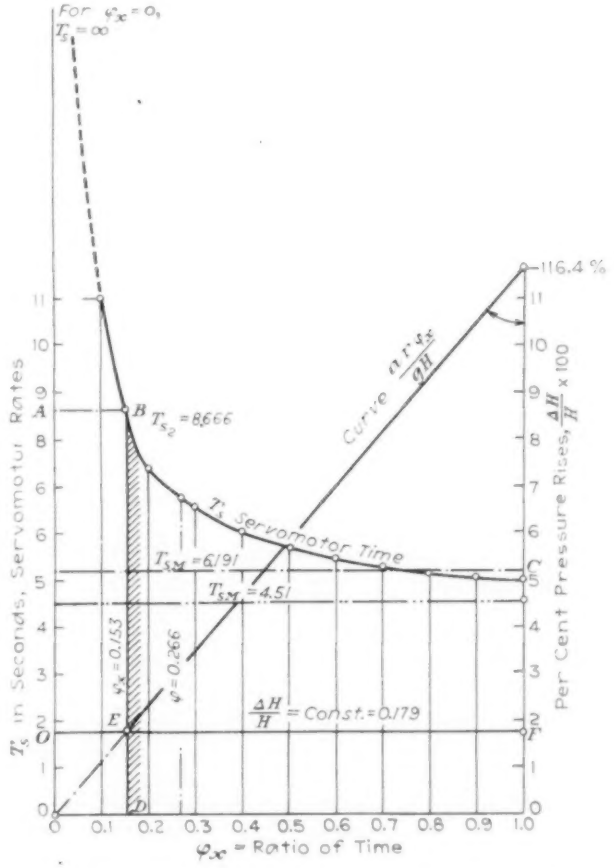

FIG. 17 SERVOMOTOR TIME T_s FOR $\Delta H/H = 0.179$; dv/dt = CONST.

Again we can write from general formula and for $T_s = 2L/a$,

$$\frac{\Delta H_x}{H} = \frac{LV \times a}{gH \times 2L}\frac{\psi_x}{\varphi_x}\frac{1}{1-\frac{1}{2\varphi_x}} = \frac{aV\psi_x}{2gH}\frac{2}{2\varphi_x - 1} \quad \ldots [60d]$$

or for $\varphi_x = 1$,

$$\frac{\Delta H_x}{H} = \frac{aV\psi_x}{gH} \quad \ldots\ldots [61]$$

or in the example,

$$\frac{\Delta H_x}{H}\frac{2000 \times 10 \times \psi_x}{32.2 \times 800} = 1.164\,\psi_x \quad \ldots\ldots [61a]$$

Formula [61] represents in general the critical momentary-pressure-rise curve. It is a straight line as shown in Fig. 16.

Again referring to formula [59a] where $\psi_x/\varphi_x = 1$ (straight-line discharge, Fig. 10),

$$\frac{\Delta H}{H} = \frac{LV}{gHT_s}\frac{1}{1-\frac{L}{a\phi_x T_s}} = \frac{LV}{gH}\frac{1}{\left(T_s - \frac{L}{a\phi_x}\right)} \quad [59c]$$

we obtain the rates of servomotor time T_s for constant $\Delta H/H$:

$$T_s = \frac{LV}{gH\frac{\Delta H}{H}} + \frac{L}{a\phi_x} \quad [62]$$

a curve of the hyperbola class $(y - M)N_x = \text{const.}$ Applied to our numerical example for $\Delta H/H = 0.179$,

$$T_s = \frac{2000 \times 10}{32.2 \times 800 \times 0.179} + \frac{2000}{3000\,\phi_x} = 4.333 + \frac{0.666}{\phi_x} \quad [63]$$

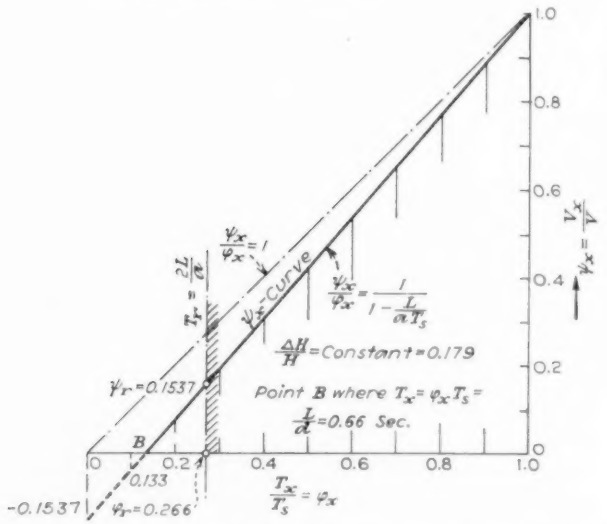

FIG. 18 VELOCITY CURVE ψ_x AS FUNCTION OF TIME ψ_x FOR CONSTANT PRESSURE RISE. $\Delta H/H = 0.179$; $T_s = 5$ SEC.

Here, for $\phi_x = 1$	$T_s = 5$
$= 0.9$	$= 5.066$
$= 0.8$	$= 5.18$
$= 0.7$	$= 5.284$
$= 0.6$	$= 5.44$
$= 0.5$	$= 5.666$
$= 0.4$	$= 6.0$
$= 0.3$	$= 6.555$
$= 0.266$	$= 6.833$
$= 0.2$	$= 7.33$
$= 0.153$	$= 8.666$
$= 0.1$	$= 11.0$
$= 0$	$= \infty$

This T_s-curve is plotted in Fig. 17 for $\phi_x = 0.153$, $T_s = 8.666$, and $T_x = T_s\phi_x = 1.33$ sec. $= 2L/a$, and according to [59b],

$$\frac{\Delta H}{H} = \frac{2000 \times 10}{32.2 \times 800}\frac{1}{8.66 - \frac{0.666}{0.153}} = 0.179 \quad [59d]$$

or at the former critical servomotor time we now obtain the desired 17.9 per cent instead of 31 per cent, by increasing the rate T_s from 5 sec. to 8.66 sec.

The critical time ratio ϕ_x for $\Delta H/H = 0.179$ is obtained from

$$\frac{aV\psi_x}{gH} = \frac{\Delta H}{H} \quad [59e]$$

and since $\psi_x = \varphi_x$,

$$\phi_x = \frac{0.179 \times 800 \times 32.2}{3000 \times 10} = 0.153 \quad [59f]$$

as shown in Figs. 16 and 17, or a servomotor rate

$$T_s = 4.333 + \frac{0.666}{0.153} = 8.666\ (59\,\text{g.})$$

This is also obtained directly from [60]:

$$T_{sr} = \frac{2LV}{gH\frac{\Delta H}{H}} = \frac{2 \times 2000 \times 10}{32.2 \times 800 \times 0.179} = 8.66 \text{ sec.} \quad [60e]$$

The momentary pressure rise of 17.9 per cent is obtained with a servomotor rate of 8.666 sec. and occurs at 0.153 of that total rate. From this point on we can close at a constant rate of $T_s = 8.666$, whereby the pressure rise $\Delta H/H$ drops in a straight line to the zero point, as shown by the dash-dot line in Fig. 17, or we can close suddenly, $T_s = 0$, whereby the pressure rise $\Delta H/H$ remains at its maximum value of 17.9 per cent, i.e., remains constant over the entire range of servomotor motion, as shown in full line in Fig. 17.

By integrating the T_s-curves and dividing by the length of the base line ϕ_x, we obtain the actual average rate T_s, or about 6.191 sec. for rates ABC with $\Delta H/H$ along lines FEO, or 4.51 sec. for rates DBC with $\Delta H/H$ along lines FEG.

From the above it follows that in order to hold the pressure rise constant the servomotor rates T_s must become longer and longer until the critical point B of the curve, Fig. 17, is reached.

The velocity curve V_x or ψ_x, as a function of the time, is obtained from formula [59], where $V_x = V\psi_x$.

$$\psi_x = \frac{\frac{\Delta H_x}{H}gHT_s}{LV}\left(\phi_x - \frac{L}{aT_s}\right) \quad [64]$$

or

$$V_x = V\psi_x = \frac{\frac{\Delta H_x}{H}gHT_s}{L}\left(\phi_x - \frac{L}{aT_s}\right) \quad [64a]$$

Thus, for a desired, constant pressure rise $\Delta H/H$ and for a fixed governor time T_s, we obtain

$$\psi_x = A\,(\phi_x - B) \quad [64b]$$

where

$$A = \frac{\frac{\Delta H_x}{H}gHT_s}{LV} \quad [64c]$$

and

$$B = \frac{L}{aT_s} \quad [64d]$$

This equation represents a straight line:

For

$$\psi_x = 0,\ \phi_x = -B = \frac{-L}{aT_s} \quad [64e]$$

$$\phi_x = 0,\ \psi_x = -AB \equiv \frac{\frac{\Delta Hx}{H}gHT_sL}{LVaT_s} \quad [64f]$$

or

$$\psi \equiv \frac{\frac{\Delta H_x}{H}gH}{Va} \quad [64g]$$

Applied to the numerical example for $\Delta H/H = 0.179$, $T_s = 5$ sec.,

$$\psi_x = \frac{0.179 \times 32.2 \times 800 \times 5}{2000 \times 10}\left(\phi_x - \frac{2000}{3000 \times 5}\right) \quad [64h]$$

$$\psi_x = 1.15276\ (\phi_x - 0.133) \quad [64i]$$

For

$$\left.\begin{aligned} \psi_x &= 0, \quad \phi_x = 0.133 \\ \phi_x &= 0, \quad \psi = -0.1537 \end{aligned}\right\} \text{ as plotted in Fig. 18.}$$

Again referring to formula [59] we can write

$$\frac{\Delta H_x}{H} = A'\left(\frac{\psi_x}{\phi_x}\right)\frac{1}{1 - \frac{B'}{\phi_x}} = \frac{A'\psi_x}{\phi_x - B'} \quad [65]$$

In Fig. 10, the rate dv/dt is constant and equal to 1. The governor reduces equal increments of Q (or v).

For values dv/dt or $\psi_x/\varphi_x < 1$, the pressure rise $\Delta H_x/H$ decreases. This may be better illustrated by reference to Fig. 19:

Curve I represents a constant rate: dv/dt or $\psi_x/\varphi_x = 1$.

Curve III represents also a constant rate but steeper: $\psi_x/\varphi_x > 1$.

Curve II has a variable rate dv/dt starting steep for the first three-tenths of V or Q.

For curve I,

$$\frac{\psi_x}{\phi_x} = \frac{1.0}{1.0} = 1.0 = 45°$$

For curve III,

$$\frac{\psi_x}{\phi_x} = \frac{1.0}{0.5} = 2.0 = 26\tfrac{1}{2}°$$

For curve II,

$$\frac{\psi_x}{\phi_x} = \frac{0.3}{0.15} = 2.0 = 26\tfrac{1}{2}°$$

for the three-tenths of curve under discussion.

For the first three-tenths of reduction of discharge we obtain a time of $T_s' = T_s \times \frac{1.5}{3} = 50$ per cent of the former time T_s.

We thus obtain from [58]

$$\frac{\Delta H_x}{H} = \frac{LV}{gH} \times \frac{1}{\left(T_s - \frac{L}{a}\right)} = \frac{2000 \times 10}{32.2 \times 800}\,\frac{1}{(0.5 \times 5 - 0.666)}$$

$$= 0.423 \quad [58c]$$

or 42.3 per cent as against 17.9 per cent, for constant rate dv/dt of curve I; or figured from the general formula [59],

$$\frac{\Delta H_x}{H} = \frac{LV\psi_x}{gHT_s'\phi_x}\,\frac{1}{1 - \frac{L}{a\phi_x T_s}}$$

we obtain for $\psi_x = 1$ and $\phi_x = 0.5$, as against curve I before:

$$\frac{\Delta H_x}{H} = \frac{2000 \times 10 \times 1.0}{32.2 \times 800 \times 5 \times 0.5}\,\frac{1}{1 - \frac{2}{3 \times 0.5 \times 5}} = 0.423$$

as before, and which is between the 3.5-sec. and 2-sec. curves of Fig. 16.

In the case of curve II the velocity decreases somewhat slower below the 70 per cent ordinate. The rate, however, starts with the same value of ψ_x/φ_x as in curve III, so that the pressure rise remains the same.

Since the pressure rise $\Delta H/H$ is a function of the rate of change of velocity, it is evident that a maximum pressure rise occurs when dv/dt or ψ_x/φ_x assumes the value $\dfrac{1.0}{\phi_x = \dfrac{2L}{aT_s}}$

so that in our numerical example:

$$\frac{\Delta H}{H} = \frac{LV}{gH}\frac{\psi_x}{\phi_x}\frac{1}{T_s}\,\frac{1}{1 - \frac{L}{a\phi_x T_s}} = \frac{2000 \times 10 \times 1 \times 3000 \times 1}{32.2 \times 800 \times 2000 \times 2\,(1 - \frac{1}{2})}$$

$$= 1.164 \text{ or } 116.4 \text{ per cent}$$

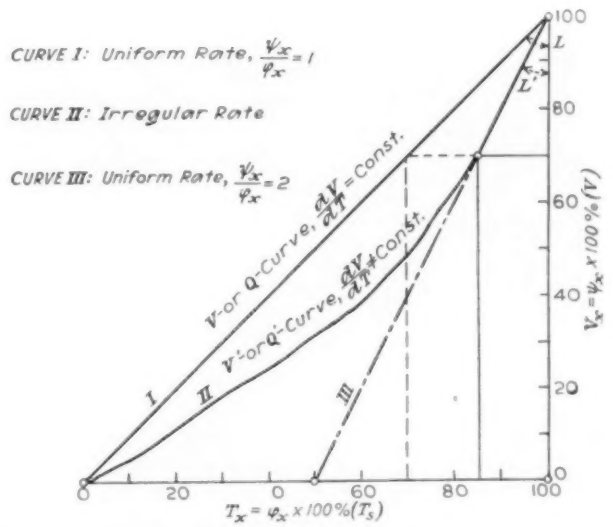

FIG. 19 DISCHARGE OR VELOCITY CURVES ILLUSTRATING CHARACTERISTICS OF RATES OF VELOCITY AS FUNCTIONS OF TIME

The important criteria to be looked out for in practice are the following:

1 The pressure rise for the last increment of complete closing motion, where T_s becomes $2L/a$, so that the momentary relative pressure rise

$$\frac{\Delta H_r}{H} = \frac{aV\psi_x}{gH} \text{ or } \frac{2LV}{gHT_s} \text{ is reached.}$$

2 The pressure rise for that portion of the closing process, where $dv/dt = \psi_x/\varphi_x$ is a maximum, and at which instants T_s' may become equal to $2L/a$

CONCLUSIONS

It can be readily seen that the problem of pressure and speed control of turbines supplied by water through closed conduits is primarily affected by the character of the discharge curve as a function of the governor time, i.e., by the rate of change (dv/dt) of velocity in the pressure supply pipe.

This rate of change of velocity in turn is fixed by the rate of motion of the turbine gates actuated by the servomotor of the governor.

The rate of motion of the servomotor in turn is fixed by the resistance of the turbine gates and by the character and action of the control valve and the speed-controlling means (or flyballs) actuating it.

All of the above elements participating in the process of

control of flow embrace individualities of action, which necessitates, as outlined in the beginning, the application of the numerous assumptions for the purpose of simplifying the mathematical problem.

It has been proved that any desired rate of change of discharge can be obtained with the rate-limiting device which provides means for obtaining that lift of control valve which is necessary to produce the desired rate of gate motion for each individual gate position.

With the possibility of so establishing in advance the character of the discharge curve, the problem becomes a surprisingly simple one, as regards calculation of pressure variations.

The critical part-gate governor time $T_r = \phi_r T_s$ for a desired maximum pressure rise

$$\frac{\Delta H_r}{H} = \frac{2LV}{gHT_s}$$

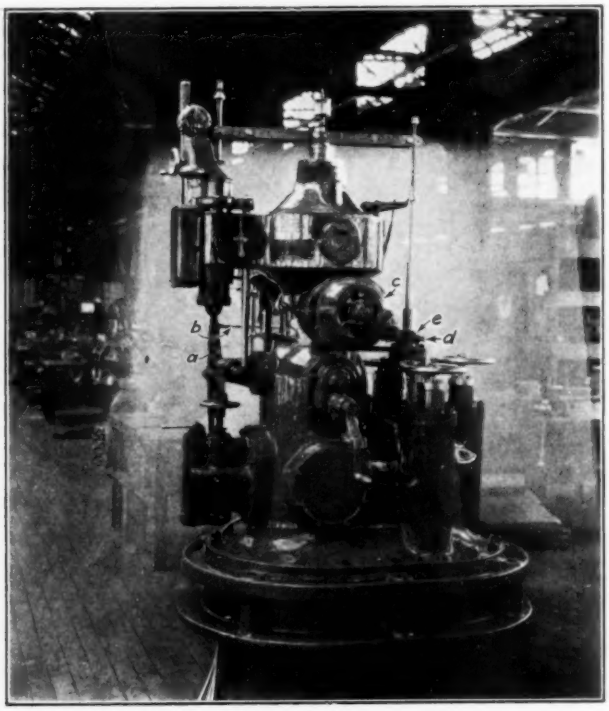

FIG. 20 TURBINE GOVERNOR ACTUATOR EQUIPPED WITH RATE-LIMITING DEVICE

for straight-line discharge, or, more explicitly, $\phi_r = 2L/aT_s$ can be calculated and the corresponding speed rise investigated.

For a limited pressure rise $\Delta H_r/H$ and a fixed head H and length L of pipe line, the governor time T_s or the size of the pipe line (V) must be selected accordingly. If for lack of flywheel effect the speed rise becomes too high for a predetermined size of pipe, then auxiliary means in the form of pressure regulators or surge tanks (to reduce ΔV in the first case and L in the latter) must be provided, or the WR^2 must be increased in order to secure a longer governor time T_s.

With the above values properly selected, it becomes a simple matter of adjusting the rate-limiting device in the field by proper determination of the maximum individual lifts y_x of the control-valve piston as previously explained. This once determined by giving the cam of the "rate-limiting" device the proper shape, assures the simplest and safest solution of the otherwise rather intricate problem. Instead of going through a series of tedious calculations, the results of which, owing to the necessity of making numerous assumptions, cannot be absolute, and only too frequently not even approximate, we can determine the surface of the cam by gradually increasing the valve lifts y_x until the desired limits of $\Delta H_x/H$ at any gate opening are obtained, a procedure which also takes considerably less time in the field than is required for making actual calculations.

The same procedure can also be applied equally effectively for independently producing opening rates satisfactory for commercial operation of the unit. The particular benefit derived from the application of the rate-limiting device is appreciated when one considers that a very slight modification of the time curves *A*, *B*, and *C*, Fig. 11, of Mr. Kerr's paper referred to before, causes differences in pressure rise of 10 per cent and even as high as 100 per cent. An application in practice is shown by Fig. 20, which is a view of an Allis-Chalmers governor actuator equipped with a rate-limiting device. The relay motion from the servomotor is transmitted to lever *a*, which actuates rod *b* and a bell-crank lever *c* with universal joint (not visible on picture because directly behind the lower right-hand part of the electric motor driving the flyballs). The bell crank *c* is link-connected to the cam *d* which can be seen projecting through the front of the control-valve cover *e*. This design is, of course, one only of many different designs which, however, accomplish the same purpose.

Appendix No. 1

EXCESSIVE pressure variations in a conduit must be avoided because of the limited strength of its material. The upper limit or maximum pressure which the conduit can resist without permanent injury is therefore fixed. It is obvious that if a conduit serves a turbine operating under a variable head, the margin between operating pressure and maximum pressure becomes smaller as the operating head approaches its maximum value. Logically, the governor closing time should then be longer in order to hold the pressure rise down so that the peak of pressure does not exceed the permissible value.

$$H + \Delta H = H_{max} \quad [66]$$

$$H + a + (\Delta H - a) = H_{max} \quad [67]$$

In the first case $\Delta H/H$ is the permissible relative pressure rise. In the second case it is

$$\frac{\Delta H - a}{H + a} < \frac{\Delta H}{H} \quad [68]$$

Similarly for a lower operating head,

$$\Delta H - a + (\Delta H + a) = H_{max} \quad [68a]$$

or

$$\frac{\Delta H + a}{\Delta H - a} > \frac{\Delta H}{H}$$

To increase the total (!) servomotor time T_s, the oil supply to the control valve is manually throttled in some installations. This reduces the possible relative pressure rise. However, in the case of a load increase immediately following the rejection, it prevents a relatively rapid opening.

W. P. Creager, vice-president and chief engineer of the Northern New York Utilities, Inc., has suggested (U. S. Patent applied) a manometric device whereby a pressure increase in the penstock throttles the oil supply and augments it accordingly as the pressure drops. Such a device will meet the requirement of Equations [66] and [67] applying to load rejections as such, and also to load increases as such, but it will not prove efficient in the case of a sudden reversal of the load change, where quick

action is desired at the very beginning of the reversal. If the oil supply to the control valve of the governor is built double-ported, with an individual supply to each port chamber, it will be possible by inserting a flat distributor gate or the like, operated by the manometric device, to increase the oil supply to the opening side and at the same time reduce it to the closing side, and vice versa.

The application of the rate-limiting device in addition to the suggested double-ported valve device will preserve the individual character of the change of rate of gate motion as a function of gate position.

The two requirements can be simultaneously met by transmitting the manometric action to the cam of the rate-limiting device in such a manner that an increase of pressure in the penstock will shift the cam surface producing the closing motion so as to reduce the individual valve lifts, and at the same time shift the opening cam surface so as to permit of greater individual valve lifts, the character of each rate curve being retained.

Discussion

Byron E. White.[5] The subjects embraced by the two papers by Mr. Arnold Pfau and Mr. Forrest Nagler merge to such an extent that a discussion of one to a certain degree involves the other. These excellent papers, together with the other papers presented at the Hydraulic Division sessions, indicate that the power industry has now grown up from childhood to manhood. The earlier installations experienced troubles which may be very aptly compared to the growing pains of youth. These papers attack some of the remaining aches and pains of this now adult phase of engineering and offer some very valuable and constructive information.

As between the two diametrically opposed schools of thought—namely, that which considers sensitive governing equipment as a prime essential for every unit and that which advocates the elimination of governors and the substitution of other means of speed control or of frequency control, such as the devices of Kerr and Warren, which school is aptly represented by Mr. Nagler—the writer is inclined to take a middle position. He is already on record to this effect, in a report entitled "Governor Problems" published by the Hydraulic Power Committee of the National Electric Light Association. To him it seems that one criterion is the existence of an isolated load, which may, either by design or by accident, be dependent for speed control upon a particular unit or units. If such is the case, a reasonably good speed-control governor is a prime essential. If, on the other hand, the plant or unit is feeding into an interconnected system and is so connected to it that when its service is interrupted it can by no possibility have an important isolated load directly dependent upon it for its frequency control, then in many instances it has been found entirely satisfactory to have the gate movement controlled by a speed-limiting or a shut-down device, lacking the sensitiveness of the usual type of hydraulic-turbine governor.

The advent of widespread interconnections between regions and plants embracing immense power capacities has made it entirely possible to throw the burden of speed control upon one or a few plants in each system. There are inherent advantages, both in single-plant control and in multiple-plan control. Fortunately, both of these systems may be operated simultaneously, in parallel, without undue voltage or frequency disturbance or undesirable interchange of power.

It is probable that frequency control will tend to take on the characteristic of multiple-plant control, because of the immensity of the systems gradually being interconnected. While each of the unit systems might have its frequency controlled by a single station or unit, when the entire system is viewed as a unit, the overall control of frequency will, in fact, be governed by a multiplicity of plants.

Intimately tied in with the control of frequency is the question of pressure rises in penstocks, which has been admirably treated by Mr. Pfau. The crux of his paper is of course the cam which he has developed, which effectually limits the rate of travel of the governor piston and consequently of the guide vanes so as to limit the pressure rises which may take place in the penstock at any portion of the stroke.

While some of the discussion centered upon the accuracy and application of the Warren formula for pressure rise, utilized by Mr. Pfau, it seems to the writer that this is but a mere side issue, since he has pointed out that at two critical points this formula coincides with that described by Mr. Kerr last year, and in the last analysis the intent of the paper is to describe a new and ingenious mechanical means of limiting such pressure rises the shape of which is determined by experiment and does not depend upon the formula except to demonstrate its action and its possibilities.

Mr. Pfau's device adds another means of accomplishing this desirable result to the others which already have been adopted and has the further advantage that its effect may be made truly variable at different portions of the governor stroke in accordance with the particular requirements which it is designed and desired to fulfil.

E. B. Strowger.[6] With reference to the mechanics of the rate-limit device, its application to the modern hydraulic governor, and the relation of this device to the rate of turbine-gate closure, the paper is to be highly commended. In the treatment accorded the subjects of pressure rise and speed regulation, however, the author has considered approximations which are not rational and which may introduce serious errors in connection with many installations.

If dN/dt equals a constant during the closure of the turbine gates, then there must be no water hammer during the closure, and consequently there must be no physical length of penstock and draft tube for this condition. The author's Equations [38], [39], [40], and [42] therefore cannot be used for accurate results. Equation [51], however, is fundamentally correct. The quantity $\int_{T=x_1}^{T=x_2} \phi dt$ in this equation should be evaluated by taking cognizance of the total excess energy transferred from the penstock to the rotating parts, as already explained in the joint article by Mr. Kerr and the writer on "Speed Changes of Hydraulic Turbines for Sudden Changes of Load."[7] With a physical length of penstock and draft tube it is impossible to justify an evaluation of this quantity by assuming a linear relation between N and T_2, as shown in Fig. 9.

The use of Warren's approximate equation would of course simplify the solution of water-hammer problems somewhat, but unfortunately its use is precluded because it does not generally apply. This has been conclusively shown by N. R. Gibson[8] and by R. S. Quick.[9] The error introduced by the approximation may be as high as 100 per cent, as shown by Quick. In particular reference to Fig. 16 of the paper, the only values

correctly given are those of the critical pressure rise labeled ΔH_r in the text. These values are plotted on the straight line which is the locus of the limiting values of pressure rise, viz., $\frac{aV}{g}$. Fig. 21 gives the correct pressure-rise curves $\Delta H_z/H$ as functions of φ_z, or per cent of time T_s for the problem given in connection with Fig. 16. As shown from this analysis, the following table gives the error in the author's use of the Warren approximation applied to this particular example, considering

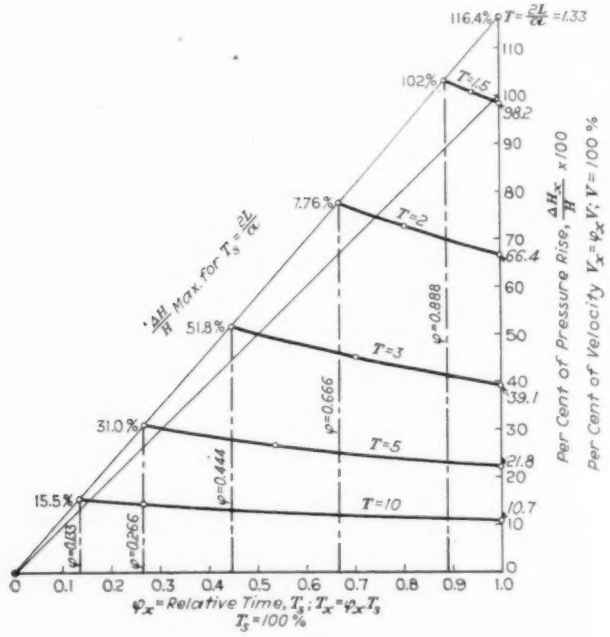

FIG. 21

the closures from $\varphi = 1$, and shows that the errors involved are as high as approximately 20 per cent:

	Pressure Rise $\Delta H_z/H$		
T_s	Pfau, %	Correct value, %	Error, %
10	8.31	10.7	22.4
5	17.9	21.8	17.9
3	33.2	39.1	15.0
2	58.2	66.4	12.3
1.5	92.8	98.2	5.5

The author intimates in his conclusions that numerous assumptions are frequently made which may be "not even approximate" and that tedious calculations are necessary for the refined methods of computing pressure rise. With reference to assumptions made in refined work and their effect upon the problem, reference is made to the article already referred to, by Kerr and Strowger. In this article it was pointed out that the calculations made for the South Falls Plant and for the Queenston plant of the Hydro Electric Power Commission of Ontario checked the actual test results remarkably closely both as regards speed rise and as regards pressure rise. The computations were based upon an analysis of the various elements of the problem which involved no assumptions except perhaps that due to a change in runner efficiency due to the speed characteristic of the turbine.

Regarding the tedious calculations necessary for obtaining pressure rise and speed rise, the writer quite agrees with Mr. Pfau that the arithmetic integration process is somewhat tedious in the case of problems involving a number of intervals of $2L/a$ seconds. However, since publishing the 1926 paper already referred to, on "Speed Rise of Hydraulic Turbines for Sudden Changes of Load," the writer has used the method of computation suggested by Quick and in this connection wishes to present the following description of this method, trusting in so doing that it will prove useful to others who have not as yet taken the time to study it. By changing from the arithmetic-integration method to that of Quick, no change in the fundamental principles is involved. The older method of arithmetic integration may be preferred by some engineers since it may be carried out by an ordinary slide rule, whereas for the other method a calculating machine or a six-place table of logarithms is necessary. However, the latter method eliminates the cut-and-try process.

Although problems in speed regulation of hydroelectric units may not assume in general the importance today which they formerly held when electric systems were more or less isolated, yet there are many special cases which involve a solution. For example, on the Niagara system due to certain tripping operations a large hydro unit may suddenly be isolated from a long-distance load and may hold on a small isolated local load or may be tripped completely from both loads. In either case there is little or no connected Wr^2 to help regulate the speed.

The change in speed in the case of a load change involving the isolation of the unit from the system is a function of the energy changes in the penstock accompanying the load change and the characteristics of the turbine runner. Thus the following factors enter the problem:

(1) Amount of the load change
(2) Head on turbine
(3) Governing time
(4) Penstock velocity
(5) Length of penstock
(6) Velocity of propagation of the pressure wave in the penstock
(7) Wr^2 of rotating parts of unit
(8) ϕ curves of turbine runner.

In the case of a load change where the unit does not separate from the system, then the connected Wr^2 of the system is effective in limiting the speed change.

The calculation consists essentially of three parts: first, the determination of the increase or decrease of head due to the load change; second, the calculation of the speed change, considering the energy changes in the penstock, but neglecting the change in turbine efficiency due to the speed change; and, third, calculating the final value of speed change, considering the runaway characteristic of the turbine. This last part of the problem can usually be omitted as the correction involved is small, as will be shown later.

The calculation of speed change uncorrected for the runaway characteristic involves the use of the formula:

$$\frac{Wr^2}{5870}(N_2^2 - N_1^2) = \Sigma \text{hp.} \times \Delta t \times 550$$

or

$$N_2 = \sqrt{\frac{3{,}229{,}000 \Sigma \Delta t \cdot \text{hp.} + Wr^2 \times N_1^2}{Wr^2}}$$

where

Δt = the time of one interval $2L/a$, sec.
N_1 = the speed at the beginning of the interval, r.p.m.
N_2 = the speed at the end of the interval, r.p.m.
hp. = average horsepower developed by turbine for the interval
W = weight of the rotating mass, lb.
r = radius of gyration, ft.

TABLE 1 COMPUTATION OF RISE IN PRESSURE FOR DETERMINATION OF SPEED REGULATION

Full load thrown off unit, 70,000 hp.
Head (H_o), 213.5 ft.
Governor time, 5 sec.
Uniform motion of regulating piston
Initial penstock velocity (V_o), 10.25 f.p.s.
Penstock length, 690 ft.
Penstock diameter, 21 ft.
Velocity of pressure wave (a), 4680 f.p.s.

$$h_{max.} = \frac{4680 \times 10.25}{32.2} = 1489.75$$

$$K = \frac{h_{max.}}{2H_o} = \frac{1489.75}{2 \times 213.5} = 3.4889$$

Table 1 gives the computation for the pressure rise in the penstock due to water hammer for a 5-sec. closure of the gates of a 70,000-hp. unit with penstock length of 690 ft. and an initial penstock velocity of 10.25 ft. per sec., using Quick's method of computation. Uniform gate motion has been used in this particular case, although it is quite a simple procedure to obtain the actual relation between time and servomotor piston stroke for any closure and by means of the relation between guide-vane opening and servomotor-piston stroke to apply the actual discharge-time curve in determining the values of ϕ_n, where ϕ_n is the proportion of initial gate factor ϕ_0 as defined by Quick.

Table 2 gives the calculation of the speed rise with no correction for the runaway characteristic of the turbine. Columns 1, 2, 3, 4, 5, 6, and 7 are obtained from the data of Table 1. Column 8 is obtained from the efficiency curve on Fig. 22 labeled *A*, which curve is based upon an actual field test of the turbine. The rest of the table is computed in the regular way in accordance with the paper already referred to. The answer of 39.0 per cent speed change appearing as the last figure in column 16 is the approximate answer and would be correct if the characteristics of the water wheel did not change during the transient speed change.

To take account of the runaway characteristic of the turbine, Table 3 has been prepared, the first seven columns of which are the same as the corresponding columns in Table 2. The revised efficiency values of column 8 are based upon the efficiency curve labeled *B* in Fig. 22, which curve has been moved from curve *A* by an amount determined from the test of a homologous 36-in. model runner. Although in the case of the example in hand the change in efficiency is of small moment and is rather erratic due to the shape of the runner ϕ curves, as shown in Fig. 23, yet the example will be worked through to a conclusion to serve as an illustration. Here ϕ is the peripheral velocity coefficient of the wheel.

From the results of Table 2 the head values and the approximate speed values for each interval (or, as in Table 4, for every two intervals) are recorded and the corresponding ϕ values computed. Knowing the relation between the gate opening on the model and the main-unit gate opening, revised values of

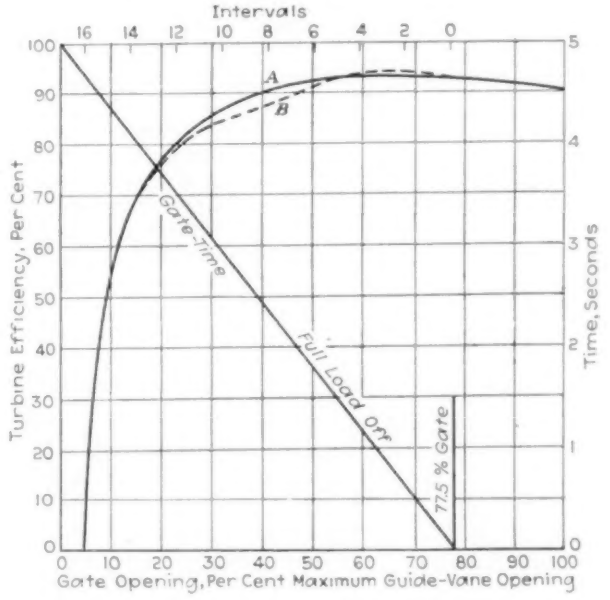

FIG. 22

model efficiency are taken from Fig. 23 for the proper ϕ value and the proper gate as given for the various intervals of Table 4. By comparing these values of efficiency with the model efficiency for the rated condition of H = 213.5 ft. and speed = 107.1 r.p.m., the change in model efficiency is found for runaway conditions existing during the load rejection, which change in efficiency is applied directly to curve *A* of Fig. 22 to obtain curve *B*. The values in column 8 of Table 3 are taken from curve *B*, and the rest of the computation is made similar to that of Table 3 resulting in the value of 38.9 per cent speed change in the place of the former value of 39.0 per cent, which was based upon no correction for the runaway characteristic of the wheel.

In this particular instance the change in speed rise caused by considering the runaway characteristic is not great, but in other cases of design a slightly larger change may result, say 1 or 2 per cent, depending upon the runner characteristics. At any rate the effect of the runaway characteristic will usually be found to be small.

The exact solution given here is not only correct from a theoretical standpoint, but has been tested experimentally by J. J. Traill, of the Hydro Electric Power Commission of Ontario, in the test work conducted at the Queenston and the South Falls Plants, already mentioned, with the result that the calculated results were closely checked.

To show what little work may be involved in a precise pressure

$$V_n = V_o \times \phi_n \sqrt{\frac{H_o + h_n}{H_o}} = V_o \phi_n \sqrt{\frac{H}{H_o}}$$

or $V_n H = V_o \phi_n \sqrt{\frac{H^{3/2}}{H_o}}$

$N_1 = 107$ r.p.m.

$Wr^2 = 70{,}030{,}000$ lb-ft.^{2}

rise computation where the number of intervals is small, the computation for one of the examples suggested by Mr. Pfau worked through by Quick's method is exhibited in Table 5. This problem is for the following conditions:

L	= 2000 ft.	$2L/a$	= 1.333 sec.
V_{max}	= 10 f.p.s.	T_s	= 2 sec.
H	= 800 ft.	N	= 2/1.333 = 1.5
a	= 3000 f.p.s.	h_{max}	= 3000 × 10/32.2 = 0.5823

Approximate methods of computation have been proposed, which methods are accurate enough for some purposes, such as for estimating work. The approximate method published in Creager and Justin's Hydro Electric Handbook is one which is satisfactory for rough work. This method employs a "type characteristic" curve for Francis runners in obtaining the runaway characteristic, instead of treating each runner independently, and also employs the impulse and momentum relation for the pressure rise without correction for the elasticity of the water or of the pipe line.

For purposes of comparison this method has been used for the problem of Tables 1, 2, and 3. The result is a speed rise of 32.2 per cent, a value as based upon the foregoing computation in error by 6.7 per cent of the normal speed change, or 17.2 per cent of the change in speed.

COMPUTATION OF SPEED RISE BY APPROXIMATE METHOD[10]

Conditions. Full load thrown off 70,000-hp. unit in 5 sec. (same condition as in Tables 1 and 3).

For open flume:

$$I = \frac{80{,}000{,}000 \times \text{hp.} \times t}{(\text{r.p.m.})^2 \times Wr^2} = \frac{80{,}000{,}000 \times 70{,}000 \times 5}{(107)^2 \times 70{,}030{,}000}$$

$$= 34.9 \text{ per cent}$$

Corrected for runaway characteristic:

$$I' = \frac{I}{100 + \frac{100 \cdot I}{r - 100}} = \frac{34.9}{100 + \frac{34.9 \times 100}{180 - 100}} = 24.3 \text{ per cent}$$

Corrected for pressure rise:

$$J = \frac{LV}{gtH} = \frac{690 \times 10.25}{32.2 \times 5 \times 213.5} = 0.2055$$

[10] See Hydro Electric Handbook, by Creager and Justin, p. 641.

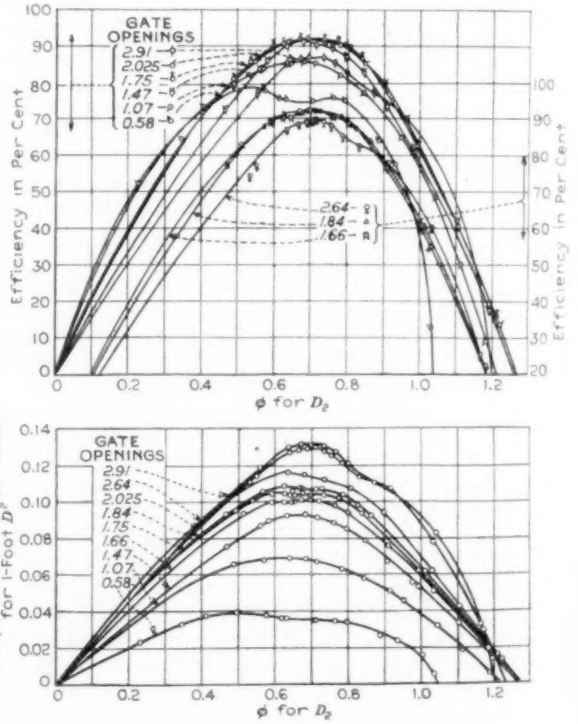

FIG. 23

$$I'' = I'(1 + J)^{1/2} = 24.3(1 + 0.2055)^{1/2} = 32.2 \text{ per cent}$$

It may be mentioned that among the problems where speed-regulation data are sometimes desirable and where accurate work may specially be desired are the following:

(1) Calculation of speed-regulation data for purposes of guarantee in connection with isolated units or units subject to isolation.

(2) Problems involving voltage rise on transmission lines.

(3) Problems involving time settings on protective relays.

(4) For calculating proper value for Wr^2 of unit.

(5) Special problems involving automatic plants and special problems with special load requirements.

The value of the author's paper, concerning the application of the rate-limit device to the hydraulic governor for controlling the rate of gate motion at any part of the servomotor stroke, should not be overlooked in discussing the mathematics of pres-

sure rise and of speed rise. The writer has had personal experience with the rate-limit device as described in connection with making a Gibson test at a hydroelectric plant. The device was utilized in obtaining pressure-time diagrams which were ideal in shape and thus expedited the work to a marked degree.

WILLIAM MONROE WHITE.[11] It seems that the discussion has diverted the attention from the main subject of the paper. Probably the author was too modest to emphasize the importance of the "rate-limiting device" which he invented, and which the writer considers to be one of the most valuable recent contributions toward a practical method of overcoming the many difficulties involved in connection with speed and pressure control of turbines, particularly when operating in connection with pipe lines.

The writer would like to point out the simplicity with which the author's device enables the obtaining of any desired rate of motion of the gate-control mechanism, as outlined in the five paragraphs on the fifth page.

Instead of depending on intricate theoretical calculations, the characteristics for assuring desired field results can be obtained in the field by the erecting engineer. He simply files down the two surfaces of the cam until, by successive tests, he has obtained that rate of governor motion which produces the permissible pressure variations in the pipe line. This procedure takes but very little time, and the adjustment, once properly accomplished, guarantees a permanent protection against pressure variations otherwise apt to be produced irrespective of results calculated in advance with the methods known today to the art.

O. V. KRUSE.[12] The portion of the paper dealing with pressure rise might rightfully be subject to criticism for the reason that the formula of Minton Warren is used as one of the determining factors. During the years 1916–17, the writer was privileged to work with Norman R. Gibson in a general water-hammer investigation, and at this time the limitations of the various theories were realized and used accordingly. As a result of these investigations, there was gained a forcible impression of the necessity of knowing the exact shape of the pressure-rise curve during turbine-gate closure. No formula seemed to satisfy the requirements except the work of Allievi, who took into account, not only the elastic properties of the water, but also the material making up the flow line. This basic consideration of elastic properties, coupled with the variable rate through the turbine gates corresponding to the pressure change, provides a complete background for determining exactly what is transpiring throughout the entire gate closure and permits of an accurate determination of all of the pressure conditions existing for various characteristics of gate closure.

The only grounds on which the subject can be treated fully and completely, in the writer's opinion, are to adhere to this theory of water-hammer determination and not resort to a simpler form of formula, such as Warren's, which is known to be very limited in its scope. Probably a mathematical solution

[11] Manager and Chief Engineer, Hydraulic Department, Allis-Chalmers Mfg. Co., Milwaukee, Wis. Mem. A.S.M.E.

[12] I. P. Morris & De La Vergne, Inc., Philadelphia, Pa.

incorporating the full water-hammer theory would be entirely impracticable, but such mathematical work can well be replaced by arithmetic integration. This system of computation is well recognized as being extremely accurate to take care of a multiple of variables. Unquestionably, a determination of the required variation in gate travel from straight-line motion could be made in this way, and if the physical characteristics of the apparatus and flow line are fairly well established, it is not out of reason that the gate motion so determined would give the desired results with little or no field adjustment.

S. LOGAN KERR.[13] The author is to be complimented upon his very detailed analysis of the method for computing pressure differences in the servomotors of a hydraulic-turbine unit due to movements of the governor valve. His analysis of the effect of the variable hydraulic load upon the operating mechanism and on the governor-valve action is of great interest.

Especially to be commended is the definition of governor rating. This value, instead of being defined as the total foot-pounds of energy that must be exerted through a full stroke, is given as the rate at which this energy is employed—namely, in foot-pounds per second. It is this value which is the true indication of a governor size, since the rate of flow through the governor determines the dimensions of the valves and piping.

The writer has used this rating for a number of years and has found it to be far more satisfactory than the overall definition commonly employed.

The rate-limiting device which the author has developed offers a very simple solution to a number of perplexing problems involving the limitation of the rate of movement of the turbine-operating mechanism. It has been our practice, however, to employ a more direct throttling system whereby the maximum rate of movement of the turbine gates is fixed, either by a diaphragm in the piping or by a positive stop on the main or pilot valve which can be securely locked in position for safety. The essential slowing up of the gate movement as it approaches the closed position is accompanied by a cushioning effect in the operating cylinder which is most effective in preventing dangerous water hammer resulting from short strokes from a small gate opening to zero. This is an additional feature of safety in that the cushion and the diaphragm are not readily subject to tampering by the operating staff. A combination of these two factors might offer a still better solution to this involved problem by having the maximum rates of the mechanism fixed by means of diaphragms and the cushion in the cylinders and still have the rate-limiting device on the pilot valve to conform to the immediate requirements for regulation.

The writer would suggest an amendment to the statements on the fifth page under headings 1 and 2, where the author describes the desired effects which can be secured by means of the rate-limiting device. Instead of the "constant rate" of piston motion, the writer would suggest "*maximum* constant rate."

The same amendment should be made under heading 2: "A *maximum* rate which produces a constant rate of change of output." By inserting this additional word in each of these paragraphs, the statement will cover all cases, since the maximum rates will be reached only when the pilot valve has made its full amount of travel.

With respect to the item 3 on this same page and with respect to section entitled, "Calculations of Pressure Rises in Pipe Lines," on the twelfth page, the writer is forced to differ very materially with the author in his assumptions. The writer's paper, mentioned by Mr. Pfau,[14] outlined in detail the method of computing the pressure rise in hydraulic-turbine conduits for all conditions of flow. The paper by Ray S. Quick[15] also is of great interest in connection with the computation of pressure-rise conditions.

In Mr. Quick's paper, the comparison of results secured from the Warren formula (used by Mr. Pfau in his presentation) was found to be markedly in error when compared with the elastic-water-column theory. This latter theory has been successfully proved in the United States by a number of experiments conducted by the Southern California Edison Company, and also through work done by Norman R. Gibson and R. D. Johnson, while in Europe a tremendous amount of work has been already accomplished which confirms beyond a doubt the analysis of water hammer by Lorenzo Allievi[16] and the work of Camichel, Eydoux, and Gariel.[17]

The essential features to point out are (1) that no single formula has as yet been developed which will give the correct result within 1 or 2 per cent of the true maximum pressure rise in a closed conduit; (2) that the maximum pressure rise is a function of the rate of change of velocity with respect to time; and (3) that the pressure rise is dependent upon the initial flow conditions from which the closure starts.

This latter fact cannot be emphasized too strongly, as it is this very feature which complicates the water-hammer studies. As pointed out in the writer's paper presented last year, three zones for water hammer are outlined, and two constants $K = av/2gH$ and $N = aT/2L$ are required.

The limits of the zones are determined by the simple relations as follows:

Zone 1—K being less than 1
N being less than 1
Zone 2—N being greater than 1
K being less than 1
Zone 3—N being greater than 1
K being greater than 1

Critical conditions are found at the common limit to zones 1 and 2—namely, at the point where $N = 1$. In both zones 1 and 2 the water-hammer studies should be carefully made to avoid dangerous pressure-rise conditions. In zone 3 the maximum pressure rise is the same for all conditions of initial flow, provided the rate of change of velocity with respect to time during closure is a constant.

In Table 1 in the writer's paper, previously mentioned, a remarkably close agreement is shown between the formulas of de Sparre-Gariel, the charts of R. S. Quick, and the arithmetic integration of N. R. Gibson. Applying Mr. Pfau's formula to these conditions, there results a very interesting agreement, as shown in Table 6.

This shows a reasonably close agreement throughout the range in flow, since this particular problem falls within the zone outlined by Mr. Quick, in which there is a reasonably close agreement between Mr. Warren's formula and the elastic wave theory.

TABLE 6

Initial velocity, ft. per sec.	Time of closure intervals	Rise in pressure, in feet: Formulas of de Sparre-Gariel	Charts of R. S. Quick	Arithmetical integration of Gibson	Pfau
10	10	51.8	51.8	51.5	49.0
9	9	51.8	51.8	..	49.4
8	8	51.8	51.0	..	49.7
7	7	51.8	51.0	..	50.2
6	6	51.8	51.2	..	50.8
5	5	51.8	53.8	54.1	51.8
4	4	58.2	59.6	..	53.3
3	3	66.5	67.4	68.0	55.5
2	2	77.7	78.5	..	62.2
1	1	93.3	93.2	93.26	93.2
0	0	0.0	0.0	0.0	0.0

However, by taking the example given on the thirteenth page of the paper, Fig. 16, a very great discrepancy has been found to exist. This is shown in Table 7.

TABLE 7

T = sec.	Rise in pressure, in feet: Allievi-Quick	de Sparre-Gariel	Error, Per cent	Pfau	Error, Per cent
10	83.9	82.2	2.03	66.5	20.7
5	180.0	174.0	3.33	143.0	18.4
3	318.0	313.0	1.57	266.0	16.4
2	523.0	520.0	0.57	466.0	10.9
1.5	783.0	780.0	0.38	742.0	5.0
1.33	933.0	933.0	0.0	933.0	0.0

It will be seen from the figures that the author's formula may be as much as 20 per cent below the true value. This is a very serious error and still further emphasizes the fact that the Warren formula is not reliable for all conditions. The accepted theories of Allievi and the formula or charts developed by Quick, de Sparre, and Gariel and the arithmetic integration method of Gibson should be used.

Author's Closure

The author is deeply indebted to Messrs. Byron E. White and William Monroe White for redirecting the attention to the most important chapter of the paper, that relating to the rate limiting device.

Mr. E. B. Strowger's comment that Equations [38], [39], [40], and [42] cannot be used for accurate results is quite correct and has been fully covered by the word "if" at the beginning of the second paragraph directly above Equation [38]. These equations were cited merely for the purpose of gradually leading to Equation [51], approved by Mr. Strowger and to which no "if"-string was tied.

A "throttling system," as cited by Mr. Kerr, located in the piping, or a positive stop on the main or pilot valve only limits the "maximum point" (the peak point, so to speak) of rate of the turbine-operating mechanism. It does not control independently both the closing and the opening rates of the control mechanism over the entire stroke, as is the case with the rate-limiting device. It is evident, therefore, that only the rate-limiting device permits of obtaining the shortest possible and therefore the most efficient rates within the permissible limits of pressure variations.

A more positive form, as preferred by Mr. Kerr, is also fully available with all the principal advantages of the proposed "rate limiting" device. It is the design by W. M. White in the form of positive displacement or throttling rods integral with the servomotor. This has already been successfully applied with servomotors directly actuating the needles of impulse wheels, where a positive and absolutely foolproof control of rate of flow of water in the high-pressure pipe line is of utmost importance (60,000-hp. impulse wheel at Big Creek 2-A and 40,000-hp. unit at San Francisquito No. 1, both in California). These rods of course also produce the cushioning effect cited by Mr. Kerr and cannot be tampered with by the operating staff. They render superfluous a combination as proposed by Mr. Kerr.

The amendment suggested by Mr. Kerr on the fifth page under headings 1 and 2 seems to be superfluous when it is realized that the name "rate-limiting device" already discloses the fact that it is a "limiting device," and as such becomes fully operative only when the full valve stroke has been attained. It is obvious that only under such conditions is the "maximum" rate obtained, and only under such conditions is the limiting effect of the device desired.

As regards the discussion of the third item, it is conceded that the Warren formula in certain cases does not furnish accurate results. A further analysis of the subject may prove of interest, with particular reference to the three characteristic cases as discussed in Mr. Kerr's paper.

Case 1: $T \leqq \frac{2L}{a}$

The general Warren formula [58]

$$\frac{\Delta H}{H} = \frac{LV}{gH\left(T - \frac{L}{a}\right)}$$

turns into $a \cdot V/g \cdot H$ for total and complete closure.

It cannot exceed the value aV/gH even if $T < 2L/a$. This checks entirely with the theories published by Mr. Kerr.

Special Case: $T_z \leqq 2L/a$ for partial but complete closures.

The transformed Warren formula [59]

$$\frac{\Delta H_z}{H} = \frac{LV_m}{gHT_s}\frac{\psi_z}{\varphi_z}\frac{1}{1 - \frac{L}{a\varphi_z T_s}}$$

with limitation $\psi_z/\varphi_z \equiv 1$ (straight velocity curve) reads [59a]

$$\frac{\Delta H_z}{H} = \frac{LV_m}{gHT_s}\frac{1}{1 - \frac{L}{a\varphi_z T_s}}$$

For $\varphi_z T_s \equiv T_z = 2L/a$, we obtain [60]

$$\frac{\Delta H_r}{H} = \frac{2LV_m}{gHT_s} = \frac{aV_m\psi_z}{gH} \quad \ldots\ldots\ldots\ldots [61]$$

These values are identical with the results obtained with formula [3a] of Mr. Kerr's paper,[4] viz., $h_n = \frac{aV_n}{g}$

$$V_n \equiv V_s = V_m\,\psi_z, \quad \text{or} \quad V_m \equiv V_s$$

$$\Delta H_r \equiv h_n$$

recommended by him, and as evidenced by the two examples cited in his discussion: (1), 93.3 ft.; (2), 933 ft.

Case 2: $\quad T > \frac{2L}{a}; \quad \frac{aV_o}{2g\,H_o} < 1$

Mr. Kerr's formula [4a] for total closure from full is:

$$h = \frac{2LV_o}{gT}\frac{1}{1 + \frac{aV_o}{2g\,H_o}\left(1 - \frac{2L}{aT}\right)}$$

and, with limitations substituted, we obtain for total full closure:

$$h = \frac{2LV_o}{gT}\frac{1}{1 + (<1)\left(1 - \frac{2L}{aT}\right)}$$

$$h = \frac{2LV_o}{gT} \frac{1}{< 2 - < \frac{2L}{aT}}$$

$$= \frac{LV_o}{gT} \frac{1}{< \left[1 - \frac{L}{aT}\right]}$$

or

$$h = \frac{LV_o}{< \left[g\left(T - \frac{L}{a}\right)\right]}$$

It will be noted that the foregoing formula is identical "in structure" with the Warren formula, and it becomes numerically identical in the special case where $\frac{aV_o}{2gH_o} = 1$ or $\frac{V_o}{2gH_o} = \frac{1}{a}$

when $\frac{aV_o}{2gH_o} < 1$, as covered by Case 2 in question, the pressure rise obtained with Warren's formula is too low, as can be seen from foregoing formula $h > \Delta H$
because

$$\frac{1}{< \left[T - \frac{L}{a}\right]} > \frac{1}{T - \frac{L}{a}}$$

For complete closure from partial gate opening Mr. Kerr's formula is:

$$h_n = \frac{2LV_n}{gT_n} \frac{1}{1 + \frac{aV_n}{2gH_o}\left(1 - \frac{2L}{aT_n}\right)}$$

If we substitute for $V_n = V_o\psi_n$, we obtain $T_n = T_s\varphi_n$

$$h_n = \frac{2LV_o}{gT_s} \frac{\psi_n}{\varphi_n} \frac{1}{1 + \frac{aV_o\psi_n}{2gH_o}\left(1 - \frac{2L}{aT_s\varphi_n}\right)}$$

for a straight-line V-curve and a proportionate governor time $\frac{\psi_n}{\varphi_n} \equiv 1$, thus:

$$h_n = \frac{2LV_o}{gT_s} \frac{1}{1 + \frac{aV_o}{2gH_o}\psi_n\left(1 - \frac{2L}{aT_s\varphi_n}\right)}$$

or

$$\equiv A \frac{1}{1 + B\psi_n - B\frac{2L}{aT_s}\frac{\psi_n}{\varphi_n}} = \frac{A}{1 + B\left(\psi_n - \frac{2L}{aT_s}\right)}$$

for the special point where $T_n = \frac{2L}{a}$ we have

$$\varphi_n = \frac{2L}{aT_s} \text{ and since } \varphi_n \equiv \psi_n \text{ because } \frac{\psi_n}{\varphi_n} \equiv 1$$

we obtain

$$h_n \equiv h_r = \frac{A}{1 + B(\psi_n - \varphi_n)} = A = \frac{2LV_o}{gT_s}$$

which again checks with the Warren formula (point b_1, Fig. 4 of Mr. Kerr's paper[4]) for values of $\varphi_n > \frac{2L}{aT_s}$ and since $\varphi_n \equiv \psi_n$

$$\psi_n > \frac{2L}{aT_s}$$

we have

$$h_n = \frac{A}{1 + B\left[> \left(\frac{2L}{aT_s}\right) - \frac{2L}{aT_s}\right]} = \frac{A}{1 + > B}$$

The values h_n are smaller than the value h_r.

For points between $\varphi_2 = 1$ and $\varphi_n = \frac{2L}{aT_s}$

we have:

$$h_n = \frac{2LV_n}{gT_n} \frac{1}{1 + \frac{aV_n}{2gH_o}\left(1 - \frac{2L}{aT_n}\right)}$$

since $\frac{aV_o}{2gH_o} < 1$ and since $V_n < V_o$
we can write:

$$\frac{2LV_n}{gT_n} \frac{1}{1 + \ll \left(1 - \frac{2L}{aT_n}\right)}$$

or

$$h_n = \frac{2LV_n}{gT_n} \frac{1}{1 + \ll 1 - \ll \frac{2L}{aT_n}}$$

$$= \frac{LV_n}{gT_n < \left(1 - \frac{L}{aT_n}\right)} \text{ or } \frac{LV_n}{< \left[g\left(T_n - \frac{L}{a}\right)\right]}$$

This is again the structure of the Warren formula. However, it proves that the values obtained are greater than those obtained by Warren.

$$\Delta H_z < h_n$$

Case 3:

$$T > \frac{2L}{a}; \qquad \frac{aV_o}{2gH_o} > 1$$

Mr. Kerr's Formula [5] for total closure:

$$h = \frac{2LV_o}{gT} \frac{1}{2\left(1 - \frac{LV_o}{2gTH_o}\right)}$$

can be rewritten as follows:

$$h = \frac{LV_o}{g\left(T - \frac{LV_o}{2gH_o}\right)}$$

Here again for the special case of

$$\frac{V_o}{2gH_o} = \frac{1}{a} \text{ instead of } > \frac{1}{a},$$

the foregoing formula goes over into the structure of Warren's formula:

$$h = \frac{LV_o}{g\left(T - \frac{L}{a}\right)}$$

or, with the author's symbols,

$$\Delta H = \frac{LV_m}{g\left(T - \frac{L}{a}\right)}$$

For $\frac{V_o}{2gH_o} > \frac{1}{a}$ we obtain:

$$h = \frac{LV_o}{g\left(T - < \frac{L}{a}\right)}$$

again demonstrating that Warren's formula in this particular case shows too low pressure rises.

Referring to Mr. Kerr's numerical example for Case 3, we have

Warren: $$\frac{LV}{g\left(T - \frac{L}{a}\right)} = \frac{600.10}{32.2\left(4 - \frac{600}{3000} = 0.2\right)}$$

$$= 49.03 \text{ ft.}$$

Kerr: $$\frac{LV}{g\left(T - \frac{LV_o}{2gH_o}\right)} = \frac{600.10}{32.2\left(4 - \frac{600.10}{2 \times 32.2 \times 233}\right)}$$

$$= \frac{6000}{32.2\left(4 - \frac{600}{1500}\right)} = 0.4$$

$$= 51.8 \text{ ft., because}$$

$$\frac{V_o}{2gH_o} = \frac{10}{32.2 \times 2 \times 233} = \frac{1}{1500}, \text{ against } \frac{1}{a} = \frac{1}{3000}$$

For complete partial closure we obtain:

$$h_n = \frac{2LV_n}{gT_n} \frac{1}{2\left(1 - \frac{LV_n}{2gT_nH_o}\right)}$$

or $$h_n = \frac{2LV_o}{gT_s}\frac{\psi_n}{\varphi_n} \frac{1}{2\left(1 - \frac{LV_o}{2gH_oT_s}\right)\frac{\psi_n}{\varphi_n}}$$

or since $$\frac{\psi_n}{\varphi_n} \equiv 1$$

$$= \frac{LV_o}{gT_s} \frac{1}{\left(1 - \frac{LV_o}{2gH_oT_s}\right)} \equiv \text{constant}$$

since $$\frac{aV_o}{2gH_o} > 1$$

it follows that $$\frac{LV_o}{2gH_oT_s} > \frac{L}{aT_s}$$

We can thus write:

$$h_n = \frac{LV_o}{gT_s} \cdot \frac{1}{1 - > \frac{L}{aT_s}} \quad \text{or} \quad \frac{LV_o}{g\left(T_s - > \frac{L}{a}\right)}$$

which again demonstrates the structure of the Warren formula, except that the value is *constant* and is greater than the value obtained by Warren for a full complete closure.

From the foregoing it seems evident that the structure of the Warren formula has maintained itself throughout the most recent publications; however, with modifications, which have brought the calculated results into closer agreement with the

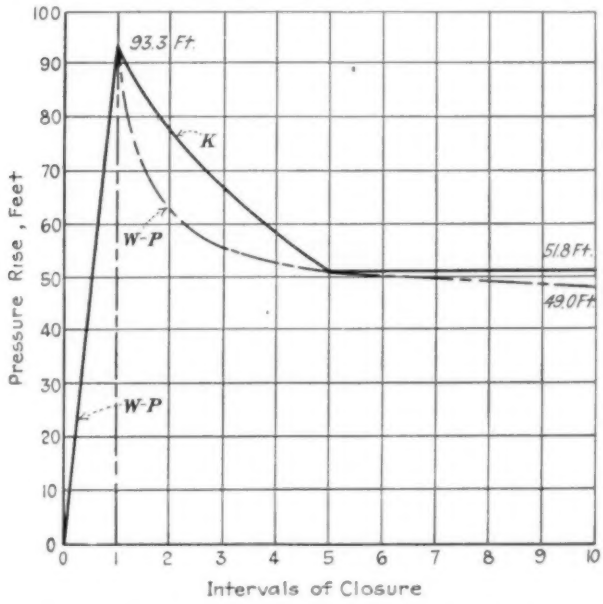

Fig. 24 Pressure-Rise Curve of Partial Closures

actual results under any possible underlying conditions. The two numerical examples tabulated by Mr. Kerr are plotted on Figs. 24 and 25.

The other comments made by Messrs. Strowger, Kruse, and Kerr, with reference to calculations of pressure variations, are fully recognized by the author, who would ask to be permitted to

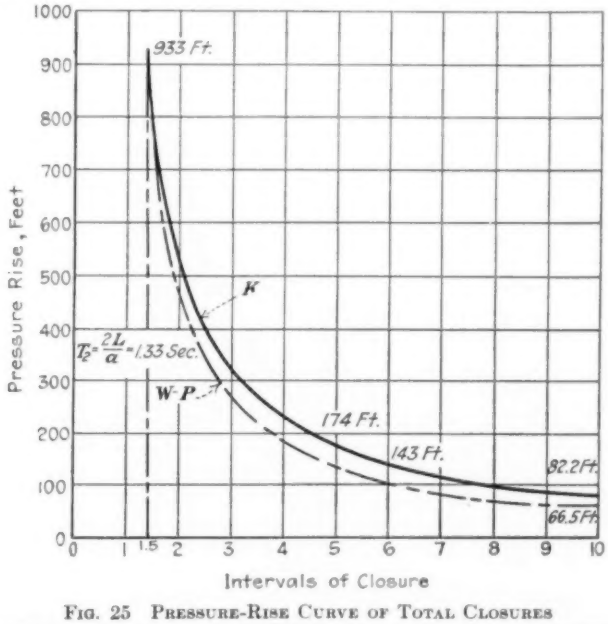

Fig. 25 Pressure-Rise Curve of Total Closures
(Note: *K* curve is according to Kerr; *W-P* curve is according to Warren-Pfau.)

state in closing that the available data relating to a natural phenomena are quite often increased in depth, and consequently in value, by an analysis of discrepancies arising out of results of independent studies.

Report of Committee on Survey of Hydraulic Research, of the Hydraulic Division[1]

THE Committee on Survey of Hydraulic Research of the Hydraulic Division of the Society was organized by the Division with Prof. C. M. Allen[2] as its chairman. A program was mapped out, and work was allocated to the several members. The members of the committee, with their respective assignments, are as follows:

R. E. B. Sharp, I. P. Morris Corporation, Philadelphia, Pa. Research in Europe.

Forrest Nagler, Allis-Chalmers Mfg. Co., Milwaukee, Wis. Water-wheel manufacturers (with R. V. Terry).

R. V. Terry, Newport News Shipbuilding and Drydock Company, Newport News, Va. Water-wheel manufacturers (with Forrest Nagler).

N. R. Gibson, Niagara Falls, N. Y. Water-power companies, exclusive of Pacific Coast (with I. A. Winters).

I. A. Winters, Alabama Power Company, Birmingham, Ala. Water-power companies of the South (with N. R. Gibson).

R. M. Peabody, Southern California Edison Company, Los Angeles, Calif. Water-power companies of the Pacific Coast.

L. F. Harza, Chicago, Ill. Research by consulting engineers (with W. F. Uhl).

W. F. Uhl, Boston, Mass. Research by consulting engineers (with L. F. Harza).

C. M. Allen, Worcester Polytechnic Institute, Worcester, Mass. Research in hydraulic laboratories of engineering colleges.

The material collected in the several fields by members of the committee is summarized in the following tables, preceded and followed by appropriate comment. After the table of research problems suggested by the committee as worthy of experimental study (some of them entirely new problems and others supplementary to experimental work already done), there is a record of research work done or being done.

Hydraulic Problems for Research

The following are hydraulic problems for research, suggested by members of the committee as coming from themselves and from those who submitted answers to questionnaires:

Problem	Suggested by	Special factors	Purpose
Relative turbine efficiency, standard test setting versus designed setting	R. V. Terry	Open flume, metal spirals, concrete spirals, concrete semi-spirals	Relate standard test, with actual operating efficiency
Effect of size on performance of turbines	R. V. Terry	Output, efficiency, best speed	Check law of similitude
Cylindrical gates outside wickets	W. F. Uhl		
Butterfly valves	W. F. Uhl		
Spiral flow (flow in spirals)	F. Nagler		
Draft tubes	L. F. Harza and W. F. Uhl[3]		Add to and correlate present knowledge
Scroll-case design	L. F. Harza	Bends in approach conduit, water passages at exit therefrom	
Mechanics of pitting	F. Nagler and W. F. Uhl[3]		Protection of runners
Lubrication	F. Nagler		Elimination of oil vapors to avoid damage to windings
Stuffing-box packing	W. F. Uhl[3]		
Intake design[4]	W. F. Uhl[3]		Make ice and debris proof. (Use models for study.)
Losses at trash racks[4]	W. F. Uhl[3]		
Friction loss in conduits[4]	W. F. Uhl[3]		
Permissible velocities in concrete water passages	R. V. Terry	Conduits, spiral cases, draft tubes	Avoid erosion
Characteristics of waves from operation of water-power plants[4]	W. F. Uhl[3]		
Movement of flood waves[4]	W. F. Uhl[3]		
Current meters[4]	L. F. Harza and W. F. Uhl[3]	Diagonal flow, disturbed flow	
Spillway discharge coefficients[4]	I. A. Winters and W. F. Uhl[3]	Shape of crest, shape of piers, head on crest, depth and approach to channel alternate and adjacent crest gates open	Increase capacity
Proper design, apron of dam	L. F. Harza	Dimensions, shape water approach, water depth, water exit	Avoid destructive wear
Hydrostatic uplift, structures on previous soils	W. F. Uhl[3]		
Design and curing concrete for dams in cold climates	W. F. Uhl	Aggregates, proportions, water-cement ratio, and consistency for placing, spading next forms on exposed faces, segregation in handling and placing	Control permeability, prevent rapid disintegration
Transportation of sedimentary material[4]	W. F. Uhl[3]		
Keep abreast of foreign developments in hydraulic research	R. E. B. Sharp	Benefit by, avoid duplication	Translation and publication of data as soon as available in the mother tongue
Disk friction	R. E. B. Sharp		

[1] Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers.

Hydraulic Researches in Europe

Researches in Europe are classified under three headings:

1 General hydraulics
2 Hydraulic turbines
3 Centrifugal pumps

Most of the data compiled are under the first two headings.

General Hydraulics

1 Disk Friction—"Resistance of Spheres and Disks at Low Reynolds Coefficients" ("Widerstandsmessungen and Kugel und Scheibe bei kleinen Reynoldsschen Sahlen"), L. Schiller and H. Schmiedel, *Zeit. fuer Flugtechnik und Motorluftschiffahrt* (Munich), vol. 19, no. 21, Nov. 14, 1928, pp. 497–501, 9 figs. Description of apparatus; results of experimental study confirming deductions of Oseen theory. E.I.S. serial no. 28, 45,149. (See comment 1.)

2 "Diverting a Free Liquid Jet on a Flat Surface," by Dr. Ing. Friedrich Reich, *V.D.I. Verlag*, G.M.B.H., Berlin, pp. 77. (See comment 2.)

3 Flow of Fluids, Theory—"Changes in Regimen of Fluids Flowing in Closed Conduits" ("Sui cambiamenti di regime nel moto di fluidi in condotti chiusi"), M. Danti, *Elektitrotechnica* (Milan), vol. 15, no. 14, May 15, 1928, pp. 374–379, 8 figs. Reviews theoretical work of Reynolds, Camerer, Lorenz, Morrow, and others on flow in cylindrical pipes and closed conduits of variable cross-section; bearing on these theories on design of hydraulic turbines. E.I.S. serial no. 28, 19,012.

4 Flow of Water—"Measure of Discharge in a Pressure Conduit" ("Mesure du debit dans une conduite forcee"), A. Schlag, *Revue Universelle des Mines* (Liege), vol. 17, no. 5, Mar. 1, 1928, pp. 215–229, 12 figs. Experimental study of different methods of measurement used at laboratory of machine construction of Liege University; treats of pitot tube and theoretical flow formulas; loss of pressure due to measuring instruments. (Concluded.) E.I.S. serial no. 28, 8116.

5 Flow of Water, Measurement—"Actual State of the Technique of Gaging" ("Etat actuel de la technique des jaugeages"), A. Bijls, *Annales de l'Association des Ingenieurs Sortis des Ecoles Speciales de Gand* (Ghent), vol. 18, series 5, no. 3, 1928, pp. 351–363. Hydrometric mills; new types and recent studies; measurement of small velocities; gaging by weirs, by

chemical means, by pressure pipes, by salt solution, and venturi meter are treated. E.I.S. serial no. 28, 44,368.

6 Hydraulic Laboratories, Europe—"Establishment and Operation of Hydraulic Laboratories" ("Inrichting en werkwijze van hydrodynamische Laboratoria"), J. W. E. C. Proper, *Waterstaats-Ingenieur* (Surabaya, Java), vol. 16, no. 4, Apr., 1928, pp. 104–112, 6 figs., partly on supplementary sheet. Report on author's study trip through Europe; descriptions and general observations of organization and operation of hydraulic laboratories in Germany, Austria, and Czechoslovakia, paying special attention to Karlsruhe laboratory and work of Rehbock; advocates establishment of hydraulic laboratory in Dutch East Indies as economic necessity. E.I.S. serial no. 28, 18,217.

7 Hydraulic Laboratories, Munich University—"Methods of Testing and Equipment at the Hydraulic Institute of Technical University of Munich," B. R. Van Leer, *Purdue Eng. Rev.*, vol. 23, no. 3, Mar., 1928, pp. 3–4, 18, 22, and 26, 1 fig. Description of plant and personnel in hydraulic laboratory of Germany's foremost university; instructions given by institute; laboratory work; administration; commercial testing; location and workshop; switch and pump rooms; physical features of laboratory; experimental instruction; research now under way; future or planned research. E.I.S. serial no. 28, 11,315.

8 Hydraulic Models—"Experimental Research at the Institute of Hydraulics and Hydraulic Construction of the Royal School of Engineering of Pisa" ("Ricerche sperimentale eseguite nell' Instituto di Idraulica e di Costruzioni Idrauliche della R. Scuola d'Ingegneria di Pisa"), G. de Marchi, *Energia Elettrica* (Milan), vol. 5, no. 4, Apr., 1928, pp. 481–489, 18 figs. Plan and equipment of hydraulic laboratory; notes on studies of models on hydraulic-jump structures; flume for study of flow over weirs; tests of models of siphons and siphon spillways. E.I.S. serial no. 28, 15,636.

9 Hydraulic Models, Chutes—"Tests of Models of By-Pass Chute of the Shannon Hydroelectric Power Plant" ("Modellversuche fuer die Schussrinne des Shannon-Kraftwerkes"), Ludin, *Bauingenieur* (Berlin), vol. 9, no. 11, Mar. 16, 1928, pp. 179–184, 9 figs. Laboratory tests of 1 to 50 models of sluice-regulated chute of about 11-m. fall, by-passing flow about turbines when plant is not operating; study of surface curves and stilling basin effect; final design determined on basis of these tests. E.I.S. serial no. 28, 10,988.

10 Hydraulic Models, Groines—"Hydraulic Experiments With Models of the Effect of Currents and Surf Breakers Upon a Sandy Sea Beach, Etc." ("Modellversuche ueber die Wirkungen der Stroemungen und Brandungswellen auf einen sandigen Meeresstrand, etc."), B. Kressner, *Bautechnik* (Berlin), vol. 6, no. 25, June 12, 1928, pp. 374–386, 33 figs. Report from hydraulic laboratory of Danzig Institute of Technology on elaborate experimental study of beach formation, design of groins and seashore protection; description of apparatus for production of wave motion, design of models of beach and groins; mechanics of surf effect, detailed topography of artificial beach. E.I.S. serial no. 28, 22,104. (See comment 3.)

11 Laboratory Research—"Application of Laboratory Research to the Study of Hydraulic Problems," by Dr. Geo. H. de Thierry, published by Massachusetts Institute of Technology, serial no. 10, Jan., 1928.

12 Orifices, Discharge—"Discharge Coefficients of I. G. Measuring Orifices for Water, Oil, Steam, and Gas" "Durchflussbeiwerte der I.G.-Messmuendungen fuer Wasser, Oel, Dampf, und Gas"), R. Witte, *V.D.I. Zeit.* (Berlin), vol. 72, no. 40, Oct. 20, 1928, pp. 1493–1503, 51 figs. Report from physics laboratory of I.-G. Farbeinindustrie Aktiengesellschaft on results of Lappe's calibration of rounded orfices and sharp-edged diaphragm orifices of pipes, from 50 to 500 mm. in diameter; comparative calibration data of V.D.I. and I.G. orifices and nozzles. E.I.S. serial no. 28, 39,063.

13 Research, Hydraulics—"The Research Institute for Hydraulic and Hydroelectric Structures," B. R. Van Leer, *Mech. Eng.*, vol. 50, no. 8, Aug., 1928, pp. 607–610, 8 figs. Account of plans and activities of Forschungsinstitut fuer Wasserbau und Wasserkraft, and experimental field of this German institution; institute proposes to be connecting link between scientific laboratory studies upon models and actual original structures in field service; it has prepared plans and drawings of buildings, channels, and experimental stations and has conducted experiments to find discharge coefficients and downstream erosion on overflow spillways and weirs. E.I.S. serial no. 28, 25,156.

14 Study of Siphons—"The Performance of Automatic Siphons" ("Sul rendimento dei sifoni autolivellatori"), E. Scimemi, *Elettrotechnica* (Milan), vol. 15, no. 13, May 5, 1928, pp. 345–351, 13 figs. Theory, discharge formulas, and discharge coefficients of siphons and siphon spillways; recent determination of coefficients of discharge of American, German, and Italian siphons; detailed report on tests of models of five Italian canal siphons, checking Froude principle of similitude and proving comparative inefficiency of siphons of sharply curved or discontinuous profiles. E.I.S. serial no. 28, 16,359. (See comment 3.)

15 Surges, Hydraulic—"Surges in Canals and Pipes" ("Om svallningar i kanaler ochtuber"), H. O. Dahl, *Ingenioers Velenskaps Akademien-Handlingar* (Stockholm), no. 63, 18 pp., 4 figs. Elementary mathematical theory of surges in open channels and pressure conduits; effect of elasticity of liquid, short and long periods of valve closure; problem of surges in open channels still unsolved. E.I.S. serial no. 28, 7510. (See comment 3.)

16 Surge Tanks—"Criterion of Stability for Differential Surge Tanks at Load Disturbances of Finite Amplitudes" ("Das Stabilitaetskriterium fuer gedsempfte Wasserschloesser bei Belastungsstoerungen mit endlichen Schwingungsweiten"), J. Schueller, *Wasserkraft und Wasserwirtschaft* (Munich), vol. 23, no. 22, Nov. 15, 1928, pp. 347–349. Theoretical mathematical discussion based on work of E. Braun, R. D. Johnson, D. Thoma, and others. E.I.S. serial no. 28, 44,940.

17 "Water Levels in Open Channels, Including Discussion of Standing Wave Phenomenon" ("Berechnung der Wasserspeigellage"), by Dr. Ing. Paul Boss, *V.D.I. Verlag*, G.M.B.H., Berlin, pp. 96. (See comment 3.)

18 Gibson Method—"The Degree of Accuracy of the Gibson Water-Meter Researches," by D. Thoma, Transactions of the Hydraulic Laboratory of the Technical University at Munich, 1926, publication no. 1. (See comment 4.)

19 Venturi Meters—"Influence of Elbows Ahead of Venturi Meters Upon the Meter Readings," Hydraulic Institute at Munich. (See comment 5.)

20 Trash Racks—"Investigations of the Loss Through Trash Racks Inclined Obliquely to the Stream Flow," Hydraulic Institute at Munich. (See comment 5.)

21 Losses in Pipe Bends—"Experiments to Determine the Loss in Right-Angle Pipe Tees, Pipe Bends, and Various Forms of Elbows," Hydraulic Institute at Munich. (See comment 5.)

22 Trash Racks—"Loss of Head in Protecting Racks at Hydraulic Power Plants," Hydraulic Laboratory at Stockholm. (See comment 5.)

23 Flow of Liquids—"Alternate Eddies Due to Obstacles of Knife-Blade Form" ("Sur les tourbillons alternes dus a des obstacles en lames de couteau"), H. Benard, *Academie des Sciences Comptes Rendus* (Paris), vol. 187, no. 23, Dec. 3, 1928, pp. 1028–1030, 1 fig. Discussion of eddies formed by thin plate submerged in liquid stream and comparison with cylindrical-body eddies. E.I.S. serial no. 28, 46,610.

24 Flow of Water, Pipes—"Tests on Loss Through Sudden Enlargements in a Water Pipe" ("Essais sur la perte par elargissement brusque dans une conduite d'eau"), L. Bergeron, *Genie Civil* (Paris), vol. 93, no. 20, Nov. 17, 1928, pp. 475–477, 4 figs. Borda theory of sudden enlargement loss conformed by tests made at Hydraulic Institute of Polytechnic School of Munich; author discusses results which concern Boda-Carnot theory. E.I.S. serial no. 28, 43,445.

Comments on General Hydraulics Articles: 1 This would appear to be a subject worthy of study and further research in this country. 2 A very complete treatise which should be available in English. 3 Should probably come more under Civil Engineering heading; see "Hydraulic Laboratory Practice." 4 The translation of this article would be desirable. 5 Are available in "Hydraulic Laboratory Practice" and will be worthy of study.

Hydraulic Turbines

25 Corrosion—"Cavitation and Corrosion in Hydraulic Problems," by Fottinger, *V.D.I. Verlag*, Berlin, 1926. (See comments 6 and 7.)

26 Corrosion—"Destruction of Turbine Blades by Wear" ("Oedeleggelse av Turbinskovler ved Taering"), H. Thoresen, *Teknisk Ukeblad* (Oslo), vol. 75, no. 21, May 25, 1928, pp. 209–214, 7 figs. Various theories as to cause of cavitation and results of laboratory experiments; stage has been reached when Francis turbines may be constructed without risk of cavitation, with reasonable specific number of revolutions for falls of average height; methods of repairing wheels damaged by cavitation. (Concluded.) E.I.S. serial no. 28, 21,110.

27 Corrosion, Discussion of Phenomenon—"Corrosion and Cavitation in Hydraulic Turbines" ("Corrosions et cavatations dans les turbomachines hydrauliques"), A. Metral, *Revue Generale de l'Electricite* (Paris), vol. 23, no. 26, June 30, 1928, pp. 403H–416H, 5 figs. Article treats of hypotheses for explaining corrosion and also phenomenon of cavitation in hydraulic turbines; reports some tests on impact action of water drops at high speeds on moving metal walls at Brown-Boveri testing laboratory at Baden, Switzerland. E.I.S. serial no. 28, 25,190. (See comment 7.)

28 Corrosion, in Hydraulic Turbines—"Cavitation Phenomena in Hydraulic Turbines," J. Ackeret. *Bul. Technique de la Suisse Romande* (Vevey), vol. 54, no. 9, May 5, 1928, pp. 99–102, 6 figs. Shows causes of low pressures occurring and localizes critical points in turbine; author considers low-head turbine having draft tube. Abstracted from *Escher-Wyss Mitteilungen*, no. 2. See English abstract, *Mech. Eng.*, vol. 50, no. 7, July, 1928, pp. 549–550. E.I.S. serial no. 28, 21,848. (See comment 7.)

29 Corrosion, Pelton Water Wheels—"Cavitation in Pelton Wheels" ("Fenomeni di corrosione nelle Turbine Pelton"), G. R. Mosca, *Energia Elettrica* (Milan), vol. 5, no. 11, Nov., 1928, pp. 1316–1326, 31 figs. Analysis of phenomenon; experience of Norwegian and Italian hydroelectric power plants; cavitation of needle valves; review of studies by Honegger, Thoma, and Camerer. E.I.S. serial no. 28, 44,292. (See comment 7.)

30 Corrosion—"Turbine and the Cavitation Problem," by Elov Englesson, *Canadian Engineer*, April, 1928. (See comment 7.)

31 Corrosion, Turbine Runners—"Destruction of Turbine Blades by Wear" ("Odeleggelse av Turbinskovler ved Taering"), H. Thoresen, *Teknisk Ukeblad* (Oslo), vol. 75, no. 20, May 18, 1928, pp. 197–201, 6 figs. Studies made to ascertain cause of wear of certain parts of turbines, especially hollows of blades; effect of vacuum and other causes; methods of laboratory established for purpose in Kristinehamn, Sweden. (To be continued.) E.I.S. serial no. 28, 17,637. (See comment 7.)

32 Design Charts for Calculating Turbines—"Alignment Charts for Calculating Turbines" ("Abaques pour le calcul des turbo-machines"), A. Schlag, *Revue Universelle des Mines* (Liege), vol. 71, June 15, 1928, pp. 280–285, 3 figs. Hydraulic turbines, pumps, and ventilators are treated, divided into six types; alignment charts are given for calculating wheels of turbines. E.I.S. serial no. 28, 23,597. (See comment 8.)

33 Design of Hydraulic Turbines (Theoretical discussion of)—"Diffuser Rings of Full-Admission Hydraulic Turbines" ("Ueber das Leitrad der Vollstrahl-Wasserturbinen"), H. Baudisch, *Schweizerische Bauzeitung* (Zurich), vol. 92, no. 3, July 21, 1928, p. 29. Theoretical discussion of principles of design; differentiates between dynamic and static (Kaplan) method of energy transmission in turbines and combination of two principles. E.I.S. serial no. 28, 27,756. (See comment 8.)

34 Dimensions—"A Method of Obtaining the Leading Dimensions and of Setting Out the Blade Forms for Hydraulic Turbines of the Francis Mixed-Flow and Propeller Types," by Herbert Mawson, Selected Paper No. 48 of the Institution of Civil Engineers (London). (See comment 8.)

35 Draft Head, Maximum Allowable on Turbine Runners—"The Highest Permissible Suction Head in Hydraulic Turbines" ("Das hoechstzulaessige Sauggefaelle von Wasserturbinen"), J. Ackeret, *Schweizerische Bauzeitung* (Zurich), vol. 91, no. 11, Mar. 17, 1928, pp. 135–136, 2 figs. Theoretical discussion calling attention to so-called dynamic suction head, which is important factor in design of Kaplan and propeller turbines and in prevention of cavitation. E.I.S. serial no. 28, 10,568.

36 Draft Tubes—"Critical Considerations of the Method of Computation and Structural Development of Draft Tubes," by Dipl. Ing. Joseph Bronner, *Wasserkraft Jahrbuch*, 1927–28.

37 Flow in Casing (Study of)—"Flow of Water in Casing of an Axial Flow Turbine," K. Kaneshige, *Tokyo Imperial Univ. Jl.* (Japan), vol. 18, no. 8, Apr., 1928, pp. 153–182, 25 figs. Flow treated is same as in Lorenz's works, but special reference is made to size of rotating core and quantity of discharge; vibration of turbine draft tube and devices for its remedies; apparatus used by writer is explained, together with experimental data from which present deductions were obtained. E.I.S. serial no. 28, 16,246. (See comment 8.)

38 Flow of Water in Turbine Runners—"Principal and Secondary Flow in Turbine Runners," by Dipl. Ing. Schilhanse Munchen, *Wasserkraft Jahrbuch*, 1925–26. (See comment 8.)

39 "Progress in Construction of Water Turbines" ("Fortschritte im Bau von Wasserturbinen"), by Prof. Dr. Ing. Alsterlen, Hannover, *V.D.I. Zeit.*, Dec. 1 and 15, 1928. (See comment 9.)

40 Kaplan—"The Employment of Propeller Turbines and Kaplan Turbines," by Dipl. Ing. G. von Troelitsch, J. M. Voith, Heidenheim.

41 "Kaplan and Propeller Turbines Compared," by Elov Englesson, A. B. Karlstadt, *Mekaniska Verkstad*, Verkstaden, Kristenhamn, Sweden.

42 "Neue Wasserturbine," by Donat Banki, *Druck des Franklin Vereins*, 1917.

43 Pressure on Runner Blades—"Investigations Regarding the Pressure Distribution on a Stepped Row of Blades," translation from "Ergebuisse

des Aerodypamischen Versuchsanstalt Zu Gottingen III Lieferung," *Druck und Verlag*, by R. Oldenbourg, Munchen und Berlin, 1927. (See comment 10.)

44 Propeller Turbines—"Air Foil Theory of Propeller Turbines and Propeller Pumps, With Special Reference to the Effects of Blade Interference Upon the Lift and the Cavitation," F. Numachi. *Soc. Mech. Engrs. Jl.* (Tokyo), vol. 31, no. 136, Aug., 1928, pp. 530–583, 4 figs. Writer has deduced the theory of these machines in light of theory of airfoil; preliminary study of theory of blade interference; theory of propeller turbines and of propeller pumps. (In English.) E.I.S. serial no. 28, 45,265. (See comment 11.)

45 Propeller Turbines—"Theory and Design of a Propeller Turbine," O. Miyagi, *Soc. Mech. Engrs. Jl.*, vol. 31, no. 136, Aug., 1928, pp. 607–615, 4 figs. Forms of casing and hub are first given, and streamline forms in clearance space are determined by making use of cylindrical coordinates; inflow velocities into runner are then calculated from streamline, and entrance and exit forms of runner vanes, to satisfy condition of minimum hydraulic losses, are determined; expressions for developing moment and power are deduced; graphical solution is introduced. (In English.) E.I.S. serial no. 28, 45,002.

46 Propeller Turbine—"The Hydro-Mechanical Fundamentals of the Axial Propeller Turbine," by Prof. Dr. Alfred Lochner and Ing. Robert Zimmermann, *Wasserkraft Jahrbuch*, 1927–28.

47 Propeller Type Turbines (Mathematical Dimensions of)—"The Propeller Type Turbine" ("La turbina helice"), J. de Ugalde Agundez, *Revista de Obras Publicas* (Madrid), vol. 76, no. 11, June 1, 1928, pp. 198–200, 8 figs. Graphs and mathematical discussion on efficiency of newest designs of turbine blades for utilization of waterfalls of slight drop. E.I.S. serial no. 28, 25,636.

48 Research—"Résumé of Interesting European Research," by B. R. Van Leer, presented at Annual Meeting, A.S.M.E., Dec., 1928.

49 Testing, Sweden—"Arrangement for Testing of Turbines at the Machine Works in Kristinehamn" ("Anordningar for provning av turbiner bid Verkstaden Kristinehamn"), H. Lind., *Tekniska Foreningens I Finland Forhandlingar* (Helsingfors), vol. 48, no. 4, April, 1928, pp. 72–81, 7 figs. Describes construction and methods of testing station for water turbines from 50 to over 1000 r.p.m., output from 20 to 90 hp.; illustrations of laboratories and accessories. (To be continued.) E.I.S. serial no. 28, 17,512. (See comment 12.)

50 Testing, Sweden (Continuation of foregoing article)—"Arrangements for Testing of Turbines at the Machine Works in Kristinehamn" ("Anordningar for provning av turbiner vid Verkstaden Kristinehamn"), H. Lind, *Tekniska Foreningens I Finland Forhandlingar* (Helsingfors), vol. 48, no. 5, May, 1928, pp. 103–108, 4 figs. Causes of cavitation; description of cavitation laboratory completed in 1924 and its testing methods; description of high-pressure laboratory and its operation. E.I.S. serial no. 28, 25,814. (See comment 12.)

51 Research—"Experimental Research in the Field of Water Power," by D. Thoma, paper no. 100 of the First World Power Conference, London.

52 Cavitation in Water Turbines—"Hydraulic Problems," by D. Thoma, published by Julius Springer, Berlin, 1926. (See comments 6 and 7.)

53 Model Turbine Tests—Description of three laboratories built by Verkstaden, Kristinehamn, Sweden, for testing large model turbines, small model turbines, for investigation of cavitation on small model turbines, and for testing impulse wheels. See appendix 4, "Hydraulic Laboratory Practice," A.S.M.E. (See comment 12.)

Comments on Hydraulic-Turbine Articles: 6 Refers to "Hydraulische Probleme" ("Hydraulic Problems.") 7 Worthy of study in connection with problem of corrosion. 8 May be of assistance to designers of hydraulic turbines, but should be further reviewed. 9 Is a most complete article dealing with foreign ideas and practice in hydraulic-turbine design. Some of the headings in this article are as follows: Improvement of Bucket Shapes; Omitting the Runner Band; Venting the Draft Tube; Shaping of Guide Vanes; Recalculation From Model Tests; High-Head Francis Turbines; Kaplan and Propeller Turbines; Efficiency With Adjustable Runner Blades; Head Limits for Reaction Turbines; Allowed Elevation Above Tail-Race Level. 10 Is a subject on which German engineers have been conducting a great deal of research. Their investigations were originally made in connection with the design of airplane wings. This article touches on the connection between tube runner vanes (primarily of the Kaplan and propeller type) and pressure distribution on airplane wings. A study of this article will show the possibilities of research on this subject. 11 Is on the same subject and should be investigated. 12 Descriptive of European hydraulic-turbine-testing laboratories.

Centrifugal Pumps

54 "Analytical and Experimental Investigations Relating to Centrifugal Pumps," by Herbert Mawson, *Proceedings of the Institution of Civil Engineers* (London). (See comment 13.)

55 "Efficiency of Large Centrifugal Pumps for Low Lifts," T. Ono. *Soc. Mech. Engrs. Jl.* (Tokyo), vol. 31, no. 136, Aug., 1928, pp. 584–606, 18 figs. Investigation of effects on efficiency of large centrifugal pumps for low lifts; angle of inlets and exit of vane; dimensions of casing; length of vane. (In Japanese.) E.I.S. serial no. 28, 44,996. (See comment 14.)

Comments on Centrifugal-Pump Articles: 13 Is available in English. 14 Would appear to be of interest to centrifugal-pump designers.

Some of the more important sources from which these data were obtained and to which attention is especially directed are:

1 "Hydraulic Laboratory Practice," by John R. Freeman, published by A.S.M.E.

2 Engineering Index Service, a current publications information service conducted by A.S.M.E.

3 "Hydraulische Probleme" ("Hydraulic Problems"), published by the Scientific Committee of the Society of German Engineers.

4 "Vorträge aus dem Gebiete der Hydro-und-Aerodynamik" ("Lectures From the Field of Hydrodynamics and Aerodynamics"), published by Th. v. Karman and T. Levi-Civita.

The Engineering Index Service has been a fruitful source of information.

The two German books are considered worthy of further careful study. To show the nature and variety of hydraulic problems dealt with, a translation of the respective tables of contents has been prepared, and is as follows:

"Hydraulic Problems"

A scientific survey; lectures given at the Hydraulic Convention in Goettingen on May 5 and 6, 1925; published by the Scientific Committee of the Society of German Engineers.

Introduction, iii.
Preface, v.
Prandtl: Report on the later researches on turbulence, 1.
Foettinger: Examinations of cavitation and corrosion in turbines, centrifugal pumps, and propellers, 14. Elementary characteristics of the cavitation process, 15. Rules for locating places of diminished pressure, 18. Physical processes, 19. Minor physical-chemical effects, 23. Injurious effects of cavitation, 25. Theory of quick corrosion and fractures, 32. Later experiments in cavitation, 34. Results of the experiments, 44. Hydrodynamic examinations, 45. Model laws and rules of similarity of cavitation, 59. Means of avoiding cavitation, 62. Final observation, 64.
D. Thoma: The cavitation in water turbines, 65. Discussion on preceding lectures, 75.
Oesterlen: The development of turbine draft tubes, 111. Discussion on the lecture by Osterlen, 122.
Fluegel: About the approximate understanding of flow losses and the bend problem, 133. Supplement, 155.
Bets: Occurrences on vane ends of Kaplan turbines, 161.
Spannhake: Application of the conformed picture in computations of flaws in turbines, 180. The problem, 180. Edge conditions for the flow, 183. Equation of moments of the turbine, 185. The determination of the whirl flow around the sero-point with circulation around the vane ends, 189. The determination of displacement flow, 190. Layer formation of flow particles, 193. Comparison with infinite number of vanes, 195. Computation of flow pictures, 198. Final observation, 199.
Pfleiderer: The final number of vanes and the impossible operating field in turbines, 201.
Thoma: Abnormal flow in measuring nozzles, 213. Discussion of lecture by Thoma, 215. Index of literature, 216.

"Lectures From the Field of Hydrodynamics and Aerodynamics"

Published by Th. v. Karman and T. Levi-Civita, Innsbruck, 1922.

U. Cisotti: About Italy's share in the progress of classical hydrodynamics in the last 15 years, 1.
L. Prandtl: About the origin of eddies in the ideal fluid, with application to the theory of carrying wings and other problems, 18.
E. Trefetz: Prandtl's theory of carrying planes and propellers, 34.
C. Wieselsberger: The most important results on the theory of carrying wings and tests of the same in experiments, 47.
V. Bjerknes: Computation of forces acting on carrying wings, 59.
E. Pistolesi: New Statements and deductions on the theory of air propellers, 67.
T. Levi-Civita: About the transport velocity in a stationary undulatory motion, 85.
W. W. Ekman: Dynamic laws of ocean currents, 97.
V. Th. Thysse: Computation of tidal waves with considerable friction, 116.
C. W. Oseen: The analytic theory of the equations of motion of an incompressible viscous liquid, 123.
Th. v. Karman: Remark on the question of the form of flow around obstacles with large values of Reynolds formula, 136.
W. Heisenberg: Non-parallel solutions of differential equations for rubbing fluids, 139.
J. M. Burgers: An experiment for estimating turbulent flow resistance, 143.
Th. v. Karman: About the surface friction of fluids, 146.
G. Kempf: The frictional resistance of rotating disks, 168.
M. Panetti: Experimental determination of the distribution of pressure on rotating level planes, 171.
B. Caldonazzo: About the uniform rotation of a solid body in an unlimited fluid, 175.
M. Panetti: Laboratory measurements of the damping moment of an airplane in light vibrations, 186.
L. Hopf: About the dynamics of airplanes, 192.
R. Verduzio: Determination of diagrams of the rise of hydroplanes on the basis of hydrodynamic experiments, 211.
A. G. v. Baumhauer: Contribution to the question of helicopters, 220.
G. Zerkowitz: About flow at velocities beyond sound velocity, 228.
D. Thoma: New perceptions of the hydrodynamics of water turbines, 240.
E. Witoszynski: About the expansion and deflection of jets, 248.

Recommendations by the Committee

The great value of up-to-date information on what is being done in other countries is quite apparent. To the end that the latest published data on research in hydraulics in those countries may be made available to American engineers at the earliest possible moment, it is recommended that—

(1) the Society assume the initiative in making a study of the means and agencies available for translation of the complete text of current foreign publications of hydraulic research, and that

(2) the Society take the necessary steps to develop and coordinate the various agencies to that end.

Research by Water-Wheel Manufacturers

Letters addressed to the various manufacturers asking about research work done by them were invariably replied to in a cooperative spirit. Extensive research work has been done and is still being carried on with the idea of improving the product to meet competition. Under the circumstances it is considered unwise to make public any information gained by individual manufacturers at great expense that could be used by competitors. It was intimated that this field of research should be reserved for the manufacturers themselves because of the large investment of time and money already made, on which there would be no adequate return in the event investigations duplicating work done or to be done by the manufacturers should be carried out and results made public. There is much to be said on both sides of such a question.

Water-Power Companies

A considerable amount of hydraulic investigation has been and is still being carried on by the power companies of the country. From this source a most generous response was received to the requests for a report on research endeavor and accomplishment. This was to be expected, since little commercial benefit could be anticipated from secrecy. On the contrary, aside from the benefit from the application and use of the new knowledge, there would be profit from publicity and good will. A summary of the returns from these letters to the power companies is as follows:

Letters of inquiry sent out	136
Replies received	74
Reporting no research	38
Reporting research	28
Reports promised, but not received	8

Research studies reported are tabulated (in a necessarily abbreviated form), as follows:

Company	Subject	Comment
Cumberland County P. & L. Co.	West Buxton, H. E. Plant	Construction features of 5000-kva. addition
Hydro-Electric Power Commission of Ontario	Engineering research	Regulation, hydroelectric units; governor action, pressure rise, speed rise, velocity of pressure wave in wood-stave pipes; hydraulic losses in large canals and power-plant intakes
Idaho Power Co.	Lifting of rotating element	14,500-hp. element lifted 25 to 32 in. on rejection of load; remedy
	Test of material for turbine runners	"Water bronze" shown preferable to manganese bronze
Marseilles Land and Water Power Co.	Current-meter measurements and discharge capacity of dam	Interrelation, gage heights, slopes and discharge; results not in form for publication
Interstate Public Service Co.	Energy dissipators at toe of dams	Results from use of tumble bay and baffle piers on dams with sand foundations
R. D. Johnson, hydraulic engineer	Johnson - Wahlman draft distributors	Theory and operation of submerged gathering tube for intakes
Kaministiquia Power Co., Ltd.	Factors affecting stream and load changes	Plan of operation of plant
Public Service Co. of New Hampshire	Stream gagings	Gaging stations installed and maintained in their territory
Manitoba Power Co., Ltd.	Development of high-speed propellor turbines	Tests to be made on units
	Flow in 90-mile aqueduct	Tests by Prof. Finlayson of Manitoba University
New England Power Construction Co.	Model tests	Spillways, intakes, valves, discharge channels, flow meters, etc.
Northern New York Utilities	Dams	Tabulation of temperature and seepage through dam
Pennsylvania P. & L. Co.	40,000-kw. hydroelectric development	Construction features of the Wallenpaupack development
Pennsylvania Water and Power Co.	Backwater computations, plant operation, and maintenance	Graphic method for computing backwater curve; experience with various materials for turbine parts; hydraulic experiment and experience data
Rochester Gas and Electric Corp.	Sector gate dams	Construction and operation of sector gate dams
St. Lawrence Valley Power Corp.	Hydraulic losses of the Allen Falls development	Tests on steel pipe line, penstock, racks, etc.
Alabama Power Co.	Increase of head at times of flood, by models, 1 to 24 and 1 to 10 full size	Head increase from 70 to 75 ft. up to floods of 200,000 c.f.s. Trans. A.S.M.E., p. 361, 1922
	Draft tube best for backwater suppressor; on 12-in. homologous runner with various types of tubes	Tube developed to use long horizontal diffuser. Trans. A.S.C.E., p. 893, 1924
	Spillway apron to prevent river-bed erosion; models of 150-ft. dam to scale 1 to 36 and 1 to 100	Developed stilling pool to absorb energy (1925–26, not published)
	Backwater curve for power house location; 1 to 100 model of complete river topography	High-water elevations established locating power house 15 ft. lower than planned (1927–28, not published)
	Design of scroll cases and draft tubes	Designs developed netting from $\frac{3}{4}$ to $1\frac{1}{2}$ per cent increase in efficiency and 5 to 10 per cent saving in cost (1927–28, not published)
Arizona Power Co.	Removal of $MgCO_3$ and other lime products from surface of flume; tests on flume itself	Development of frames with wire brushes and springs shaped to section; towed by current buckets and returned by light cars
U. S. Dept. of Int., Bureau of Reclamation, Denver, Col.	Model studies of concrete dams tested under mercury load; Stevenson Creek test dam	Verified feasibility of design from study of models. Proc. A.S.C.E., May, 1928, part III, vol. 1, of Arch Dam report; 1927 to date
	Determination of data for use in design of dam; installation of pressure pipes and measurement of pressure in dams	Data on uplift pressures under dams on various kinds of foundation. Proc. A.S.C.E., March, 1928, p. 685; tests 1916 to date
	Discharge coefficients for use in design; various heads and openings	Not compiled, tests 1925 to date
	Channel and spillway design; experiments on model and on spillway of Arrowrock Dam	Established design method based on laws of momentum. Trans. A.S.C.E., vol. 89, p. 881; tests 1923–24
	Determining of data for use in determining evaporation losses from reservoir surfaces	Water losses by evaporation more accurately determined. Trans. A.S.C.E., vol. 90, p. 266; tests 1905 to date
	Data for use in design of new irrigation projects by measurement of water use on existing projects	Produced a compilation of water-use data. To be published in Proc. A.S.C.E.; tests 1905 to date
	Valves, reduction in size, and amount of metal, and amount of housing space	Metal in valves reduced over 30 per cent; dimensions of of valves and structures reduced. Washington Specifications No. 480, balanced needle valves for Echo, Gibson, and Coolidge Dams: Studies 1926–28
	More efficient and economical spillway device for Owyhee Dam	Hydraulically controlled floating ring around a central discharge orifice. *Eng. News-Record*, Apr. 28, 1928, p. 663
Byllesby Eng. and Man. Corp., Kentucky	Coefficient of friction, earthfill cofferdam on smooth limestone ledge river bottom; 1 to 10 model, water rising slowly on one side	Sliding resistance as great as overturning; tests 1925
	Comparison, permeability of well-made concrete with concrete given coat of liquid waterproofing; by immersion and increase in weight	No special merit in the waterproofing; tests 1925
	Method of building cofferdam in constricted width with heavy current	Tight forms, 2-ft. concrete wall, braced, held 6 ft. of rapidly moving water; studies 1926
Tennessee Electric Power Co.	Stop leaks through seams in limestone rock under dam	Hot asphalt through electrically heated pipes effective in stopping portion of leakage; tests 1920–24.

	Eng. News Record, May 20, 1926
Removal of sand from water to reduce wear in runner clearances	Water from penstock through centrifugal sand separator admitted to annular space around clearance rings displacing sand bearing water; eliminated sand wear of clearances
To dissipate the energy of spillway discharge to prevent river bed erosion; by models	Concrete tumble-bay designed successfully to destroy kinetic energy
Performance of runner under 35-ft. and 70-ft. head; water flow by salt velocity	Runner designed for 35-ft. head adapted to efficient operation under 70-ft. head; studies 1927

Research by Consulting Engineers

There is an apparent lack of interest among consulting hydraulic engineers to whom questionnaires were addressed, as evidenced by the small number of replies received. Only four answered, and only one of them had anything to report. It is possible that these engineers lack the facilities, the organization, and the time that the large companies and engineering colleges have, and that they have to depend upon the published information from these latter sources. The researches reported by the one engineer referred to are:

Albert C. Arend, consulting engineer, Omaha, Neb.	Study of deposition and erosion for tailwater conditions during seven years at a small hydroelectric plant on the Cedar River at Fullerton, Neb.
	Deposition of rock and silt bars from flood flows and pondage back of dam on North Branch of the Big Blue River at Milford, Neb.; continuity of flow and effect of same on tailwater elevations at the upper or Milford Dam
	Water-surface gradients between Holmesville and Blue Springs Dams, 8 miles apart in the Big Blue River, Neb.; to settle a controversy on tailwater interference.

Research by Hydraulic Laboratories

Replies to questionnaires were received from twenty-nine colleges, two commercial laboratories, and one consulting engineer. The reports from these, as summarized, show thirteen of the colleges carrying on no research whatever and many of the rest only a limited amount of work. The commercial laboratories carry on research in only a limited field, and the results are not made public. A digest of the replies to questionnaires is as follows:

Armour Institute of Technology, Chicago, Ill., Prof. G. F. Genhardt	Nothing because of limitations of equipment
Associated Factory Mutual Fire Insurance Companies, Boston, Mass., H. B. Stewart, Asst. Engr.	Hydraulic work done by these laboratories is for the most part tests on valves and other equipment used in fire-protective equipment
The Polytechnic Institute, Brooklyn, New York, Prof. H. P. Hammond	Not made any researches in hydraulics
Brown University, Providence, R. I., Prof. W. H. Kenerson	Commercial tests on venturi meters and one or two syphon spillways, as well as discharge from special model weirs
California Institute of Technology, Pasadena, Calif., Prof. R. L. Daugherty	Some work on siphon spillways; flow of water from street gutters through openings in the curb into the storm drains below
Case School of Applied Science, Cleveland, Ohio, Prof. R. H. Danforth	Laboratory not planned for research work; none done
Cochrane Corporation, Philadelphia, Pa., Percy S. Lyon	No research information
Colorado College, Colorado Springs, Col., Prof. F. M. Okey	No research work
Columbia University, New York City, Prof. R. T. Livingston	No real non-professional research. Commercial tests and investigations: (1) Rotary-pump development tests for J. B. Russell & Assoc., New York City; (2) calibration of large-ratio pipe line orifices for fluid meters, for Leeds & Northrup Co., Philadelphia
Harvard University, Cambridge, Mass., Dean H. J. Hughes	(1) Effect of corrosion on the discharge of small pipes of different materials together with an investigation of the roughness of pipes; (2) the hydraulic properties of filtering materials
Robert E. Horton, consulting hydraulic engineer, Voorheesville, N. Y.	Experimental study of flood waves; experiments on the permeability of soils
University of Illinois, Urbana, Ill., Prof. M. L. Enger	Comparative tests of friction, losses in cement lines, and tar-coated pipe; the variation of pressure in a manifold pipe; experiments on relief valves; carrying capacity of vertical pipes; piezometer in pipe lines
State University of Iowa, Iowa City, Iowa, Prof. Floyd A. Nagler	Flow of water through culverts; investigations on the accuracy of various types of current meters; experiments pertaining to the discharge of the Keokuk spillways; flow of water around bends, flow of water around bridge piers; weir investigations; tumble-bay and hydraulic-jump experiments; flow conditions at the free outlet of conduits; river water-surface elevations; hydraulic-jump experiments; backwater suppression and head-increaser experiments; flood-wave experiments; hydraulic tests on flap gates; tile-alignment tests; effect of diagonal channel obstructions
Johns Hopkins University, Baltimore, Md., Prof. J. H. Gregory	Work not done on sufficiently large scale to be of importance
Lafayette College, Easton, Pa., Prof. Lynn Perry	Flow of water and air in pipes and through standard connections such as valves, published in *Engineering News-Record*, May 29, 1924, and Feb. 12, 1925; loss of head in standard valves, open and partly open and standard pipe of various sizes; this work has been done for loss of head in the flow of water and the flow of air; this latter will be published shortly; also some research work in connection as well as the structural strength of various types of materials of which open channels are usually constructed

Power—Steam or Hydro, or Both

By WM. W. TEFFT,[1] JACKSON, MICH.

Emphasis is placed on the necessity of including all pertinent factors in a comparison of steam with hydro power, drawing attention to the fact that any conclusions based upon a part of these factors will be erroneous, misleading, and valueless. In considering the various factors that go to make up the final conclusion attention is called to the superiority of steam power where need for power is immediate, where the more profitable hydro sites have already been developed, and where the actual load factor is very high. It is also made clear that hydro power is superior in reliability and as reserve capacity, and can operate to advantage at a much lower load factor than can steam. It might be said that the paper deals largely with load factor. Curves based upon a large number of developments in each case indicate that usually for 60 per cent load factor or less the hydro plants are superior, the statement being made that no steam plant can now be built for 25 per cent load factor that will produce current for 1 cent per kw-hr., but there are many water-power plants, most of them in fact, that can do this.

It is concluded that there is ample proof that a power system combining both steam and hydro plants can generate power cheaper than either kind of prime mover.

SO MUCH has been written in the last decade, and particularly recently, about the relative merits of steam and of hydro power and their cost that it would seem as though the various subdivisions of this subject had been presented adequately. If this paper succeeds in setting up a simple and accurate way of determining when to build steam or hydro or both, and how much of each, its purpose will have been accomplished. The apparently widespread propaganda in the semi-technical and popular press in favor of steam power, with its benefits to miners, mine owners, railroads, and manufacturers of steam equipment, as well as politically, is not a part of this discussion, but only the overall cost of power delivered to the customers' meter, which is where the revenue is collected.

Whether steam has been coming into its own is practically settled by the facts that hydro power last year was just over 40 per cent of the public-utility total, and that it increased 20 times over the previous 25 years, whereas steam increased but 14 times over the same period. (See Bibliography, 38.) Whether steam or hydro or a combination of both will be developed in the future should depend, it would seem, on which of these three will deliver the cheapest reliable power to the customers' meter. In the interest of simplicity the problem also will be limited to electric power for public-utility systems, since it represents some 55 per cent of the power of the country, which is as much as all the rest of the world (35) and is typical of most all other power development. Also electric power systems make possible the most advantageous use of both kinds of prime movers. The problem resolves itself into two factors: 1 Economics of a combined system. 2 Determination of proportion of steam and hydro in such a combined system.

[1] Consulting Engineer, Vice-President, Fargo Engineering Co. Mem. A.S.M.E.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

ECONOMICS OF A COMBINED SYSTEM

In general it has been conclusively shown and described in the technical press that the cost of power in a combined system is less than it would be if the total amount were supplied by either (10, 16, 23, 27, 33, 36, 38, 44); this is evidenced by the existence of many combined systems representing as they do the conclusions of separate groups of engineers. This is only evidence, as the solutions of yesterday will not do today or for tomorrow. The trend, however, is indicated. The total cost of steam power, including all fixed and operating charges, has not lessened greatly in the last few years, the gain in efficiency being just about offset by the fixed charges on its increasing cost and the increasing cost of fuel (44, p. 34). Unit hydro construction costs have increased somewhat, and a high efficiency of over 92 per cent has obtained for some time. Just here it should be noted, though, that the rapidly changing design of steam plants introduces a very high obsolescence charge to offset in some large proportion their gain in efficiency. There is scarcely a steam plant in the country ten years old but is obsolete. Hydros have permanence. Few, if any, well-designed hydroelectric plants ten years old but are turning out power cheaper than new steam plants in their neighborhood. Of course the cheaper dam sites were developed first.

DETERMINATION OF PROPORTION OF STEAM AND HYDRO

Now to attempt here a definite determination of the proper ratio of steam and hydro in a system, or even to illustrate with a specific instance, would be misleading and valueless. A parallel checking list of pertinent items is intended to set up a weighted outline that may be applied to specific cases to arrive at the proper proportion of steam and hydro. It cannot include everything, but is based upon intimate and extensive experience and avoids prejudice and undue emphasis on isolated factors. Usually the most economical ratio is obtained when some spilling of power water is necessary during high-river stages.

COMPARISON OF STEAM AND HYDRO

This checking list is as follows:

CONSTRUCTION COST

Steam.—Steam usually less than hydro per kilowatt of machine capacity. Should include transmission investment necessary to deliver current to place in system comparable to hydro (34, p. 1207; 30).

Hydro.—Hydro usually more than steam per kilowatt of machine capacity. Should include transmission investment necessary to deliver current to place in system comparable to steam. One of the most promising opportunities for the reduction of construction cost lies in reducing interest during construction.

TIME REQUIRED FOR DESIGN

Steam.—Should be designed as construction proceeds to avoid obsolescence amounting to close to 10 per cent per year. This increases construction cost, but not as much as the 10 per cent.

Hydro.—May have ample time, as efficiency does not change much from year to year.

FINANCING

Hydro.—Hydro securities are more easily sold than for steam. The amount of earnings allowed by utilities commissions is based upon the physical value of the property, say 8 per cent of it. Then as hydro costs more per kilowatt than steam its owner is automatically allowed to earn more than on a kilowatt of steam, perhaps three times as much. This on the premise that the kilowatt-hour cost is the same as or less than with steam.

TIME REQUIRED FOR CONSTRUCTION

Steam.—About half as long as hydro.

Hydro.—About twice as long as steam.

POPULARITY

Steam.—Smoke and cinders and ash are unpopular. Also, the warming of streams is not desirable. Manufacturers sell more equipment per kilowatt for steam than for hydro. Coal miners, mine owners and railroads receive greater benefits.

Hydro.—The hydro is usually popular because: (*a*) Its cost is largely spent in its neighborhood. (*b*) Fishing is usually bettered. (*c*) The shoreline

becomes available for summer homes. (*d*) Taxes are more than for steam. (*e*) Securities seem to sell easier.

Fixed Charges

For purposes of comparison to determine kilowatt-hour costs, fixed charges should be combined with operating charges and load factor.

Steam.—Interest, 6%; taxes, 2%; depreciation and obsolescence, 10% (the present economical life of a steam turbine is 40,000 hours or 5.5 working years). (See Bibliography, 50.) Total, 18%.

Hydro.—Interest, 6%; taxes, 2% or less; depreciation and obsolescence, 2%. Total, 10%.

Operating Charges

For the purpose of comparison to determine kilowatt-hour costs, operating charges should be combined with fixed charges and load factor.

Total Charges

Only total charges are logically comparable. For purposes of comparison to determine kilowatt-hour costs, total fixed and operating charges should be combined with load factor.

Reliability

Steam.—Steam plants are not so reliable as hydro, thus requiring more reserve capacity on this score.

Hydro.—Hydro plants are mechanically two and one-half to six times as reliable as steam plants at their respective switchboards, and from two and two-tenths to five times as reliable if the interruptions of 100 miles of modern transmission line are added to the hydro plant. (Wm. W. Tefft Report, January, 1924; 7, N.E.L.A. Report, June, 1925; 12, N.E.L.A. Report, May 17–21, 1926; 20, N.E.L.A. Report National, February, 1927; 22, Hydroelectric Handbook, Creager and Justin, p. 874; 40, N.E.L.A. Report, May, 1929.) Hydro plants need reserve prime movers for low-water periods. These may be steam or hydro pumping plants.

Reserve Capacity

In determining the kind of reserve capacity hydro pumping plants are more reliable and usually cheaper than steam.

Steam.—Requires reserve capacity on account of inferior reliability of steam. Say, add 20 per cent to plant capacity for reserve; this is irrespective of load factor as a steam plant has no storage as does a hydro.

Hydro.—Requires reserve capacity on account of low water. Load factor affects the amount to be determined for comparative purposes. For a plant operating at 50 per cent load factor, the reserve capacity will need to be but one-half as much as for 100 per cent load factor, assuming pond storage for 12 hours.

For comparative purposes, hydro usually requires approximately 30 per cent of its capacity, net as reserve over steam.

Pumped Storage Hydro Plants

Steam.—Pumped storage plants, where economically feasible, make ideal reserve for steam plants as they are immediately available in emergency and improve the load factor on the steam plants.

Hydro.—(31, 39, 45, 49)—Where topographic conditions permit, hydro pumped storage plants can be built for from $60 to $80 per kilowatt and having an overall efficiency of 60 per cent. They often are economical for hydro reserve as well as for steam.

Load Factor

Steam.—The cost of steam power is greatly affected by change of load factor. A plant producing power at a total cost of 0.75 cent per kilowatt-hour at 50 per cent load factor will not be able to better 1.15 cents per kilowatt-hour at 25 per cent load factor, an increase of 53 per cent in cost for a change of but 25 per cent in load factor.

Hydro.—(Fig. 3; 29, p. 475; 36)—Hydro is very much superior to steam as variation of load factor has but a negligible effect on the cost of power per kilowatt-hour. Because of this, the cost of power from interconnected system plants is greatly reduced by the hydro plants.

The foregoing list of items to be considered in any competent study of the relative merits and value of steam and of hydro power, together with the abbreviated comments on each, is intended to emphasize the error in trying to arrive at a conclusion by considering only part of these items. No conclusion of value can be reached by considering that fixed charges on hydro are greater than steam or by considering only that operating charges on steam are greater than for hydro power. Nothing less than a summary of all of the factors involved can be of any great value in determining whether steam or hydro power is better. Construction costs, financing, time required for construction, popularity of securities, fixed charges, total charges, reliability, reserve capacity required, pumped storage hydroelectric plants, and last, but by no means least, load factor, all are vital parts of such a determination.

The construction costs, time required for design, financing, and time required for construction, all have a bearing on the first cost. While the first cost of steam per kilowatt is usually less than for hydro, the operating charges tend to equalize them, so that the summation when considered on the basis of total annual kilowatt-hour may show little difference. During the last few years the gain in steam efficiency has been very marked and rather uniform, while the gain in hydro efficiency has been very little, as there is not much more to gain. This gaining of steam efficiency has had the effect of increasing the percentage of fixed charges applicable to steam plants due to obsolescence. It is not a part of this paper to go extensively into the matter of depreciation and obsolescence, as it is a subject by itself, but there are few if any steam plants in this country ten years old but are obsolete although perhaps in perfect mechanical operating condition. The present economic life of a steam turbine is but 5.5 working years (50), so it would seem that the economics of any new power installation on a system, steam as well as hydro, should be based upon the system load factor rather than upon any assumption that the new turbine on account of its high efficiency will carry the base load for a term of years. The next new plant would take its place. Thus the depreciation and obsolescence item for steam would be at least 10 per cent, whereas for permanent high efficiency hydro plants 2 per cent is ample,

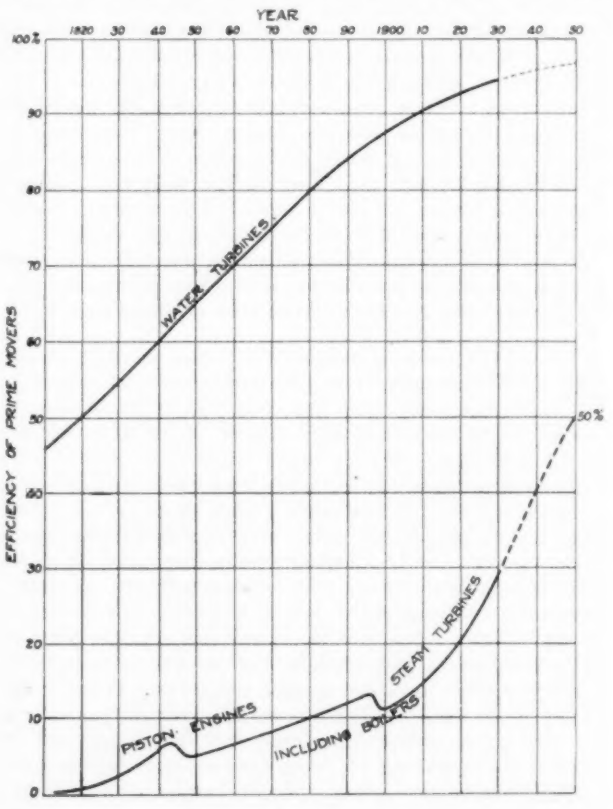

Fig. 1

making the total fixed charges for hydro 10 per cent and for steam 18 per cent.

Relative reliability is of the utmost importance. According to experience and the figures representing composite data for the entire country, steam stations may be expected to have an outage of 8.2 per cent of the time when their service is really needed as compared with a hydro plant and its modern 100-mile transmission line to load center, having a similar outage of 1.33 per cent of the time, which gives a ratio of 6.16 (W. W. Tefft Investigation, 1923–24; 7, 12, 20, 22, 40).

Even if the figure for the steam unit only is used, without any penalty for all the rest of the steam station, there is a ratio of 3.34 to 1.33 or 2.5. On the basis of these figures it seems conclusively proved that a hydro plant with its 100-mile transmission line and accessory apparatus will have only one-fourth or one-fifth of the outage of necessity as a steam plant at the load center. Also, it should be borne in mind that with the ever-

increasing size of steam units the practice of carrying one unit in reserve is a much greater financial penalty than holding a hydro unit in reserve, since the latter is usually of much smaller capacity with proportionately smaller fixed charges.

The inferiority of reliability of the steam plant as compared with the hydroelectric plant and its transmission line is, the author believes, quite typical of the two methods of generating power. A steam plant, with its multiplicity of machines operating at high speeds, high pressures, high temperatures, high metal stresses, and severe and repeated temperature changes, hardly could be expected to be as reliable as the extremely simple hydroelectric units operating at low speed.

A hydroelectric plant of three units can be put into operation in an emergency from no load (stationary) to full capacity in less than four minutes, while a steam plant, even with the boilers banked, would require thirty minutes or more, usually one hour.

The matter of superior hydroelectric reliability extends beyond the hydroelectric plants themselves, and renders the steam plants and also the transmission lines more reliable, inasmuch as an interruption to service in a steam plant can be made up for ten hours or more by the hydro pondage, and likewise an interruption of one transmission line can be made up for by drawing on the stored water and by the increased loading of another transmission line.

Both steam and hydro plants require reserve capacity, but for different reasons: the hydro on account of decrease in stream flow, and the steam on account of inferior reliability. The reserve capacity required for hydro plants on account of lack of reliability is negligible, inasmuch as they have been shown to be 98.7 per cent reliable when needed. If in the comparison of this item the hydros could be charged with all of the reserve required on account of diminishing stream flow, then the steam should be charged with all of the reserve required for any purpose, such as annual shutdown for inspection and cleaning of boilers, and all plant apparatus affecting the kilowatt output; 20 per cent reserve for an all-steam-generating system would appear reasonable. Reserve for hydro plants depends upon the load factor at which they use the available water, which, at low water time under economic operation, would not be more than 50 per cent. The reserve capacity required to keep the needed output up to the plant capacity would be the difference between plant capacity and the power in kilowatts that low water could develop at 50 per cent load factor. For comparative purposes hydro in the Middle West requires approximately 30 per cent of its capacity as a reserve over what a steam plant would require for the same capacity.

The reserve capacity may take the form of steam plants designed cheaply for that kind of service only; the utilization of steam plants obsolete for base load purposes; additional hydro plants or pumped storage hydroelectric plants. Of these the pumped storage hydroelectric plants, where topographic conditions permit, appear to have merit.

"There has recently developed an intensified interest in the economic possibilities of peak-load hydroelectric plants, making use of water which has been wholly or in part pumped into storage above such a plant during off-peak periods. This has come about through the recent completion of the Rocky River plant of the Connecticut Light & Power Company near New Milford, Conn., which has at present one 24,000-kw. unit and provision for a second unit of equal size. While it was well known that some 45 plants of this kind had been constructed abroad, it seems that it required the evidence of a successful venture in this country to stimulate power engineers to a detailed study of possible locations for similar peak-load plants in their own territories, only three in this country having come to attention—namely, the Rocky River plant, the Mill Creek plant in Utah, and the Tule River plant in California. A number of large hydro pump plants are being designed in the United States, and construction will probably be undertaken in some instances in the near future." (49, H. S. Hunt.)

They cost usually from $60 to $80 per kilowatt and make ideal reserve for steam plants as they are immediately available in emergency, and improve the load factor on the steam plants.

This storing of energy by means of pumping water makes feasible the development of tidal power at costs below five mills per kilowatt-hour and at either low or high load factors.

Load factor is not by any means the only advantage accruing to hydro development, but it is one of the most important. The determination of the relative merits of hydro or steam developments rests on the cost of power per kilowatt-hour delivered into the power system. On a purely annual kilowatt-hour basis there may not be much difference in the Middle West, where, of course, the cheap sites were developed first. This, however, is not quite the way to analyze their relative merits, as under these conditions with the proper analysis hydro will be the cheaper. A hydro plant properly designed can be operated on a very low load factor, particularly at the low-water periods when its power is most valuable. This one characteristic, and there are several others that will not be mentioned here, is of very great importance. By operating the hydro plants on an interconnected system at a low load factor the load factor on the steam plants is greatly increased and consequently bettered, so that one of the greatest advantages of hydro development, and it is an important advantage justifying very careful and thorough study in every instance, lies in reducing the cost of steam power rather than the actual generation of cheaper hydro power.

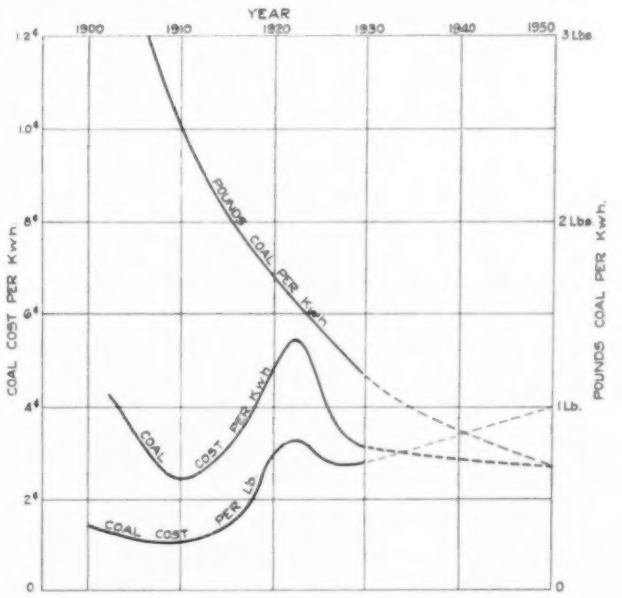

FIG. 2

The two summary curves on Fig. 3, one showing the total steam cost and the other the total hydro cost, plotted against load factor, have a background of some 58 operating hydro plants and over 30 steam plants. From these two curves it will be seen that the cost of steam and hydro power are about equal at 65 per cent load factor on the basis of load factor only, and without giving to hydro any other advantage, such as reliability. For a load factor of around 49 per cent, which is close to the usual system load factor, the direct differential in cost shown

by the curves is some 7 per cent in favor of hydro, without taking any advantage of the bettering of the steam load factor by the hydro.

For instance, if the cost per kilowatt-hour at the proper location on a system, including all operating and fixed charges, is 0.7 cent for both steam and hydro when each is supplying, say, one-half of the required power, the average cost, of course, would be 0.7 cent. If, however, a hydro plant is made to operate at a low load factor, thus bettering the load factor on the steam plant, the cost of the hydro power would still remain at approximately 0.7 cent, but the cost of the steam power might drop to 0.54 cent, thus making an average cost to the system of 0.62 cent, or a reduction of total cost to the system of over 11 per cent.

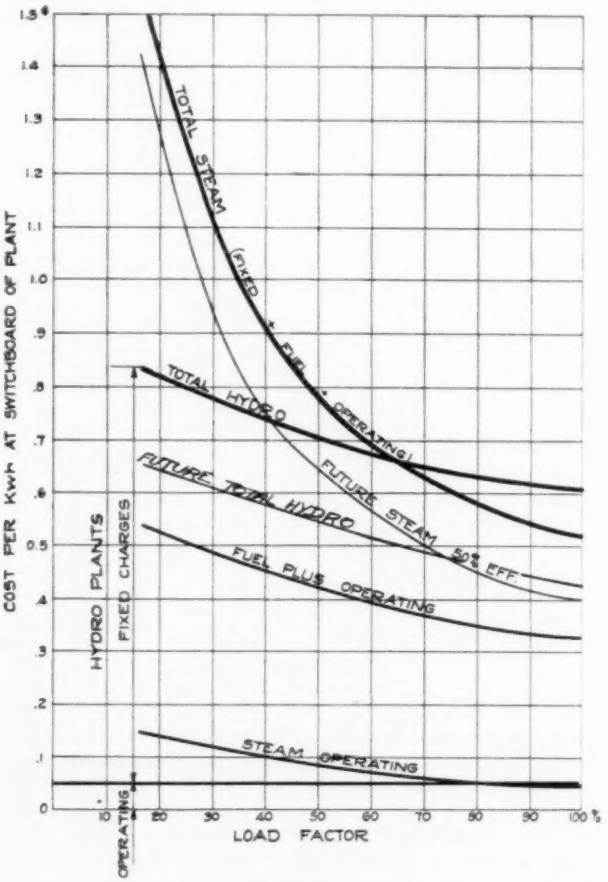

FIG. 3

The cost of power in the future from steam will probably remain about constant, on the assumption that steam-plant efficiencies will gradually increase until they reach 50 per cent in 1950. This assumes that efficiencies will increase somewhat faster in the future than has been the case in the past, although there does not now seem to be much evidence to indicate that the increase will be any faster than it has been. On this assumption, on Fig. 3 there is shown a curve indicating the approximate future cost of steam power for various load factors. Another curve on the same figure indicates the future hydro cost based only slightly upon decrease in construction cost, but mainly upon expected increase of stream flow during the next quarter of a century. In further comparing steam and water power a condition inherent to water power should be emphasized which will materially enhance the value of water power during the next 25 years.

Fuel can be fed to steam stations according to requirement, but in most hydraulic stations water is supplied according to the existing sequence in the natural supply. This natural supply is variable, often within wide limits. The output of hydraulic stations, for instance in Michigan during 1928, was 1,143,397,000 kw-hr. Had the flow of rivers been as in 1925, the output would have been some 400,000,000 kw-hr. less. The return on the investment in a hydraulic station is dependent on the average annual power output and its load factor. Should this average shift to higher levels, the total cost of hydraulic power as denoted by the curve (Fig. 3) will move downward and eventually below the cost of steam power at all values of load factor.

The expectation for the next 25 years is exactly that. The data and considerations involved are too voluminous to be presented here in full, but may be indicated briefly. Gradually it has been realized that trends and oscillations are visible in hydraulic data which follow definite sequences not traceable in weather data. Meteorology deals chiefly with momentary values, while hydraulic data are cumulative. Water is collected on large drainage areas and partially runs off into storage basins or lakes, where it is again accumulated. While weeks of dry weather follow short periods of rain, river flow continues uninterrupted, following only the cumulative values of rainfall. Lakes exhibit important changes of level during long periods, though the faint climate cause is not felt in the weather.

It appears that these small climatic changes, negligible in meteorology but highly important for water-power engineering, can be correlated and used to estimate the future trend. (See U.S.G.S. Water Supply Paper No. 30, by Lane and Horton 1899, p. 28, which contains an estimate of an exactly verified minimum three years in advance.) Based on the researches of Prof. Edward Bruckner (see "Climatic Changes Since 1700," Ed Holzel, Vienna, 1890), they have been extended and utilized for practical purposes (see A. Streiff: "On the Investigation of Cycles and the Relation of the Bruckner and Solar Cycle;" "Notes on Estimating Runoff;" "The Practical Importance of Climatic Cycles in Engineering;" *Monthly Weather Review*, Washington, D. C., July, 1926; March, 1928, July, 1929).

The long cycle appears to have attained its minimum from 1895 to 1915, which minimum extended over the whole North American Continent; during which period the most vigorous development of hydroelectric power occurred. Hydroelectric power is now facing a period of increased flow, which increase for some localities as southwestern Texas and southern Michigan is estimated to average some 40 per cent during the next 25 years. This is due to the amplifying effect of stream flow over rainfall (see Fig. 5). The examples shown indicate that an increase in rainfall of 30 per cent may double the runoff, the latter increasing three times faster than the rainfall.

A 33 per cent increase in runoff would immediately bring the curve of cost of hydraulic power below the cost of steam power, at 100 per cent load factor and twice the present efficiency of steam plants. A 16 per cent increase would reduce the cost of hydraulic power below that of steam plants at all load factors.

It appears, therefore, that the future of hydroelectric power, viewed from this angle and at least for the next 25 years, is bright.

CONCLUSION

There is ample proof that a power system combining both steam and hydro plants can generate power cheaper than either kind of prime mover for the same conditions, thus indicating the mutual advantage of one to the other. The percentage of each must be solved for in each individual case, the emphasis of the solution being upon including all of the pertinent factors

with their proper values. Throughout the country steam power is being developed perhaps three times as fast as hydro power, partly because the better hydro sites were developed first and so the remaining ones are not so profitable, but mainly because this appears to be somewhere near the proper ratio of steam and hydro. Hydro power generated in 1928 is 40 per cent of the public utility total, being an increase of about 8 per cent over the preceding year. In the future steam plant efficiencies will increase; the cost of obtaining them will increase also, and it would seem that the prospect of hydro continuing to maintain its percentage of development is still bright. A study of the prospect of increased flow of rivers, with the magnified effect that this would have upon the hydro-power output and the development of cheap tidal power at almost any desired load factor through the aid of hydro pump storage, indicates rather clearly that it is to be expected.

Many of the hydro developments that appeared at the moment to be most profitable have been developed. As conditions changed, however, some that appeared less profitable then have become more profitable now, such as Conowingo on the Susquehanna River near Philadelphia.

If the progress of the art should eliminate a part or all of the cost of transmission, most of the benefit would accrue to the hydro.

There can be no force to the statement or propaganda that water power is declining when 40 per cent of the power of the nation is hydraulic, and when the largest concentrations of power in this country are hydraulic, and when the future looks fully as bright for hydraulic as for steam. Neither can there be any force in the statement that steam will be superseded when there are localities in which no hydroelectric is possible, nor in the statement that steam is cheaper than hydro when it is more economical in many places on this continent to develop steam with hydro power than with coal. In fact, nothing less than a complete analysis of all of the cold facts will arrive at the proper conclusion. Hydro will continue to be profitable as long as the present conditions of load factor exist. Few, if any, power systems have load factors higher than 50 per cent, and many of them much less. No steam plant can now be built for 25 per cent load factor that will produce current for 1 cent per kw-hr., but there are many water power plants, most of them in fact, that can do this.

Discussion

ARNOLD PFAU.[2] The author has touched upon the subject of "pumped storage." Our country should pay a little more attention to these possibilities, particularly because it will surely prove to be a valuable contribution toward an increase in economy in connection with large, combined power systems.

In Switzerland, the writer understands, they are now introducing the use of a so-called "national bus bar," to which all electric energy can be delivered which otherwise would have to be wasted by private utilities as well as by municipal or government hydro plants.

Owing to old established rights, the benchmarks of the rivers are closely fixed, so that water-power owners must be careful to avoid interference with their neighbors. They must not back up into the tailrace of the party above, and they cannot hold back water which might lower the headwater level of the party below. Thus, many low-head plants operating at night at a very low load factor have to open the waste gates in order to hold the water levels within permissible limits.

With the adoption of the national bus bar, these plants, without any appreciable increase in operating expenses, can deliver the full stream-flow output, thereby not only increasing their own revenue but enabling plants located elsewhere and operated from reservoirs to shut down completely during off-peak hours. Not only can the prime movers of some of these plants be shut down, but surplus energy is available to operate pumps and thus replenish the storage, so that a larger peak-load capacity becomes available.

As our trunk transmission-line system develops, it will also become possible to build pumping storage plants in locations best suited for most economic development, so that the river-flow plants can dispose of their surplus off-peak output.

BLAKE R. VAN LEER.[3] The author has presented in a thorough manner a subject of vital concern not only to the engineering profession, but to our country at large. There are other aspects of this subject which were purposely omitted from his paper because they are intangible and incapable of measurement. The writer refers to the political and social aspects of steam power as compared with hydro.

To one who is familiar with public opinion of the nation as reflected by the actions and discussions taking place in our national Congress, there can be no doubt that there exists in America today a decidedly large and growing determination upon the part of the people to preserve and conserve our natural resources. This attitude is frequently advanced and advocated even though the cost may be exorbitant.

There is not the slightest difference of opinion on the point that every time a ton of coal is burned under a steam plant some small part of our natural resources has gone forever. When power available in our rivers is not used in the generation of hydroelectric energy, every hour that such use is not made means the loss of a portion of our natural resources. In other words, if we do not use our coal today, we may yet use it tomorrow, but if we do not use our hydro energy today, that particular energy has gone forever.

This argument seems to carry great weight with the people of the nation, and they are definitely determined to see that our natural resources are conserved. This means that they will advocate the development of hydroelectric energy even though it does not show a financial return in comparison to coal. This is one of the political aspects of the question.

There is another equally important phase of this question; it is the social aspect. This brings about the development of communities and industries in very interesting and peculiar ways. Most hydraulic engineers are familiar with the situation as it exists in California. There the large cities and popular centers are found along the seacoast, and the hydroelectric energy is located in the mountains several hundred miles to the east. Between the mountain range and the seacoast lies a series of valleys, which, were it not for irrigation made possible from wells and rivers flowing through the territory, would be little more than desert. However, because there is little coal in California and oil is a comparatively recent discovery in that section of the country, hydroelectric plants were built in the mountains and threaded through transmission lines, crossing what were once unproductive valleys, in order to reach the populous centers on the coast which use the principal amount of the energy generated in the mountains.

This made it possible for farmers and many small consumers to have in these arid valleys a cheap source of electrical energy running almost through their fields. The amount of energy which these people at first used was so small that it would have been uneconomical to have built a power line to them, but since the power line must cross their fields in order to get to the cities, it of necessity became available.

Thus we find that a large, useful, and productive civilization has grown up in what were once arid desert valleys in California, and this growth has been produced in no small measure by the development of California's hydroelectric energy. Had steam power exclusively been developed in the large cities in California it would have been many years before the interior valleys would have reached the growth and prosperity which they enjoy today.

[2] Consulting Engineer, Allis-Chalmers Manufacturing Company, Milwaukee, Wis. Mem. A.S.M.E.

[3] Assistant Secretary, American Engineering Council, Washington, D. C. Mem. A.S.M.E.

Thus it is seen that in some special cases the development and use of hydroelectric energy may have a very vital and significant influence upon the social development of a state.

ABRAHAM STREIFF.[4] Never before in the history of hydroelectric power has Europe witnessed such a large-scale expansion of water-power development as at the present time. While in the United States it is being debated whether steam or hydro installations are more economical, in Europe water power is experiencing an unparalleled boom.

This expansion of water power is occurring in the face of the ceaseless refinements in steam power, which now is entering upon an era of higher pressures and temperatures with greater economies, most of which are in advance of American practice. We may mention the high-pressure steam generators of Loeffler, Schmidt, Brown-Boveri, Benson; superheat up to 850 deg. and pressures up to 3200 lb. per sq. in.; the steam accumulator of Ruth; the steady development of the Diesel engine. The turbine locomotive of Ljungstrom is there in daily use; the Swiss Federal Railways now operate locomotives having 850 lb. boiler pressure.

In spite of this intensive development of steam, European hydro is expanding on an unprecedented scale; for the steam plant in its present form has its natural limitations. Every improvement is an added complication to a system already filled with the most varied machinery and piping. Coal consumption decreases, but complication and cost increase. Sixty per cent of the heat equivalent of coal is still wasted in the 450 tons of cooling water that must be pumped for each ton of fuel burned. The removal of soot and cinders assumes costly proportions. With fuel supply subject to strikes and wars and to ever-increasing cost, it is small wonder that hydro power in Europe is at present at the pinnacle of its development.

That situation presages the future of the United States, where now the natural resources are wasted at the most reckless rate ever seen. Coal and oil may be plentiful and comparatively cheap at present, but just as surely as the forests are vanishing, fuel deposits are disappearing, fuel costs increasing, while water power remains undiminished and conserves the land by equalizing and storing floods. These considerations are in Europe already of such importance as to give rise to the construction of an increasing number of huge water-power stations. A few of the latest ones may be named:

Ryburg-Schworstadt on the Rhine; 112,000 hp.; annual output, 500,000,000 kw-h.

Oberhasle, Switzerland; 244,000 hp.; annual output, 538,000,000 kw-h.

Kembs, Alsace; 120,000 hp.

Shannon River, Ireland, 228,000 hp.

Kardaun, South Tyrol; 285,000 hp.; annual output, 500,000,000 kw-h. This plant has a modern settling basin, system Dufour, for a discharge of 3150 c.f.s.

Ill Works, Austria; 300,000 hp.; to be transmitted to the Westphalian industrial region at 220,000 volts. The maximum head of this system is 4400 ft.; the main reservoir also receives water from an auxiliary stream pumped against 1300 ft. head. The transmission line, the first European line of 220,000 volts, will serve to interchange power made from white or black coal as needed. Here we find the author's conclusion of a combined system as the best solution exemplified in a new large development.

The basic causes of such hydro expansion as now occurs in Europe are less pronounced here, but in this country too a boom in water power is in sight. It is caused by an unexpected, old, but newly recognized factor, the climatic cycle.

Long discounted by the meteorologists as unimportant for purposes of weather service, it assumes important dimensions for the future of hydroelectric power supply. The cumulative nature of run-off and the amplifying effect of a stream flow on rainfall changes vary the mean value of stream flow and hence the mean value of power derived therefrom. The great development of hydro in the last 25 years occurred at the lowest point of the long, so-called "secular" cycle, and the expectation for the next 25 years is that stream flow will pass through the high point of that cycle, as it did in the 70's and 80's, and before that.

That future stream flow can be estimated many years ahead has been demonstrated. The late Professor Bruckner, geologist of the University of Vienna, wrote his book, "Climatic Changes Since 1700," in 1887–90. In that work he discusses the future of the climate in the Great Basin, Utah (p. 286), and states: "Undoubtedly the next minimum will occur toward the end of the century (1900). These regions face a time of crop failures which, according to press reports from the United States, has already commenced."

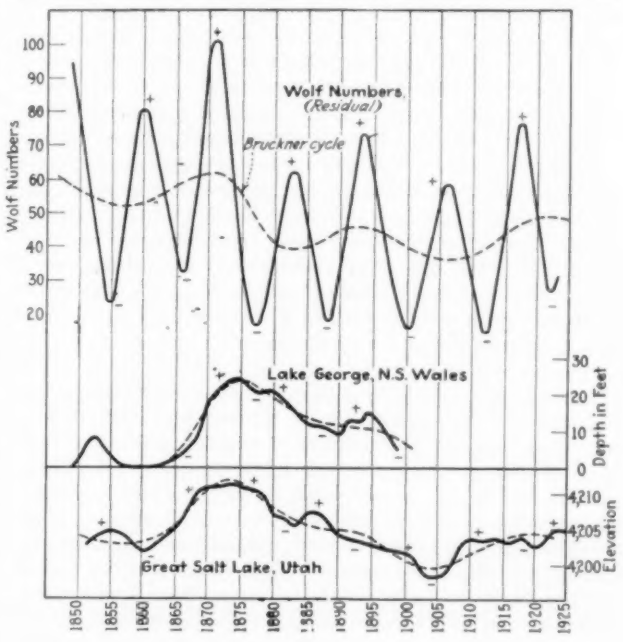

FIG. 6

The graph of the Great Salt Lake (see Fig. 6) shows that the estimate was exactly verified. The lake fell sharpest around 1900 and has risen ever since 1905.

But also in American hydraulic literature do we find examples of such prognostication. In Water-supply paper No. 30, 1899, p. 28, Mr. Robert E. Horton states of rainfall in the Kalamazoo region, Michigan: "A fifth minimum may be expected around 1901." This expectation pronounced three years ahead was also exactly verified.

The increase in stream flow is expected to culminate around 1945. This does not mean that the flow of streams will be uniformly at high levels, but the mean values will be higher than at present and with these the output of water power. In lower Michigan the run-off, around 1945, is expected to average double of that around 1910.

It is of interest to compare the history of water and steam power in this region. In 1912 a dam was built on the Ausable River. This dam is now, after 17 years, in perfect running order with its original machinery (maximum 85 per cent efficiency) in place. It was constructed for about $800,000; it would cost more than twice that today. This dam has produced uninterruptedly an

[4] Stevens & Wood, Inc., New York, N. Y.

average of 35,000,000 kw-h. during this time. During the next 25 years that average is expected to be greatly increased, without one dollar of additional expense, through the agency of the climatic cycle.

A steam plant on the same system was built in the same year, 1912. This steam station has now been completely dismantled and replaced by a modern installation. The original investment is practically without returns. The power cost of the new installation will in the next 25 years rise with the price of coal and the increase in wages.

Nevertheless, as the author emphasizes, the best combination was reached by the use of both and has furnished uninterrupted power supply for 17 years.

A system fed by steam power alone cannot have a load factor greater than that of the daily load curve. Hence the increase of steam power while decreasing hydro will thwart the possibility of operating steam at higher load factors and eliminate the only condition under which steam can be more economical than hydro—namely, at high load factor. Without auxiliary hydro, steam power is doomed to operate at uneconomical load factors below 50 per cent, which is the usual case of the American power system.

While this applies to a large section of the country, comparative merits of steam and hydro are necessarily regional. The abundance of natural gas and crude oil in California greatly favors the use of steam power, while no steam power can possibly compete with the rates at which firm hydroelectric power is obtainable in Eastern Canada, namely, $15 per hp. per year or 2.3 mills per kw-hr., and where in consequence steam is made by hydroelectric power for industrial use.

Edwin H. Brown.[5] The author has marshaled his statements in a brief and concise style that is commendable, but tends to imply that the paper is a summary of accepted facts. It is true, as the author says, that generally a ten-year-old steam plant is obsolete, but in judging the plans for future power generation the reason for obsolescence should be thoroughly sought. Thus the 1920 steam plant is not obsolete, because coal costs more now than it then did, as the author's Fig. 2 shows that the cost of coal per ton is the same now as ten years ago. A new steam plant has been built because the load has increased and the old plant has become a standby. The new plant is more efficient because the steam engineer has always available an increased head. This could be best shown if the author had included in his Fig. 1 a head curve for the steam plant. Such a curve would have shown that in the year 1800 the steam plant rendered available to its prime mover a head of about 130,000 ft. and that in 1930 this head would be over 475,000 ft.

It would appear that for a system with an increasing load the comparison of steam- and hydro-plant installations should weigh carefully the investment of capital in a hydro plant against which only 2 per cent for depreciation and obsolescence is charged. The increase in steam pressure (or head) in a steam plant is accompanied by an increase in capacity for given physical dimensions of apparatus and may result in no increased cost for the gain in efficiency that is made.

The increasing load that has been mentioned as being primarily responsible for the new plant that renders the old one obsolete has also tended, in American practice, to make modernizing extensions to old steam plants obsolete. If the load increased at a less rate than it has done in the past, it is entirely conceivable that more work would have been done in enlarging and improving older plants in some of the ways that have been described in the technical press and in papers on the subject. For instance, in an older steam plant, the pressure could be increased and a turbine be put between the new boilers and the lower-pressure turbine. This would modernize and enlarge the plant, as steam-turbine efficiency has been high for over ten years, and no great loss would result from using the older turbine as the lower-pressure stages of the modernized plant. Such work, if done, would reduce the apparent obsolescence of the steam plant that is now ten years old. It has, in all probability, not been done extensively because the rate of increase of load, together with load factor, has made it undesirable.

It seems that the author could well have touched on the influence of increasing load on capital expenditures.

[5] Assistant Manager, Steam Turbine Department, Allis-Chalmers Manufacturing Co., Milwaukee, Wis. Mem. A.S.M.E.

Joel D. Justin.[6] The paper is of great interest at this time when there is so much in the public press about the utilization of our undeveloped water powers. The writer is particularly interested, as he has spent much of his time in the past several years in connection with problems involving the coordination of these two principal sources of power.

Steam and Hydro Complementary, Not Competitive

As a result of many investigations, he is convinced that in any section of the country where suitable hydro sites exist the load curve of a large power company can be more economically supplied by a suitable combination of hydro and steam plants than by steam plants alone. It is unfortunate that these two sources of power are usually considered as competitive. This is so only in a very limited sense. Their relationship can be better expressed by saying that they are complementary.

Steam Plants for Base Load, Hydro for Peak

Usually, steam plants should be installed primarily for the base load and hydro plants to take the peaks. During times of high water, the position is temporarily reversed, and the hydros supply the base and the steam the peak. This makes it highly desirable that the steam base load should be sufficiently large to permit full absorption of the available hydro energy at times of high water. The increment cost of energy for a modern steam plant is low, and in most cases new peak-load steam plants are seldom justifiable. This is because at small additional capital expenditure a highly efficient steam plant can be built and assigned to the base of the load, resulting in a high annual capacity factor. The old steam plants are then raised up on the load curve or held in reserve and generate a smaller number of kilowatt-hours per year. There are a few hydro plants, like Niagara, which are suitable for constant base-load operation, but such plants are rare. The usual hydro plant with pondage must be conceived of as primarily suited for taking care of the upper portion of the load curve, which may have a load factor of 10 to 40 per cent.

Basic Reason Why Hydros Are Suitable for Peaks

There is a basic economic reason why hydro plants with pondage are particularly suited to take care of the upper portion of the load curve which has a relatively low load factor. The greater portion of the investment of hydro plants is in items independent of the amount of the capacity installed, such as the dams and the lands required. Thus, at a given site, on a given river, it may cost $200 per kw. to provide an installation on a 60 per cent load-factor basis during the low flow week, but additional capacity may often be installed at a cost of $40 to $70 per kilowatt-hour. If the capacity which it is proposed to provide will do the same work on the load curve as alternative steam capacity, it merely remains to determine whether the proposed hydro installation can serve this portion of the load curve more cheaply than additional steam capacity.

[6] Hydro-Electric Engineer, United Gas Improvement Company, Philadelphia, Pa.

Extensive Economic Study Required to Determine Advisability of Hydro

Any load can successfully be served exclusively by steam capacity. Consequently, when new capacity is required, the obvious thing to do is to provide more steam capacity. If, however, it is proposed to build a hydro plant to serve a portion of the load, a rather extensive economic study is required to determine whether the proposed hydro project would be more economical than to provide additional steam.

Firm Capacity of Hydro Plant

For this reason it is desirable to set up the proposed hydro project on a steam alternative basis. The first question to determine is what portion of the hydro capacity that it is proposed to instal can be relied on to perform the same function on the load curve as alternative steam capacity. This portion of the installed capacity is usually referred to as firm capacity. It may be determined for any given year by a study of the system-load curves at times of maximum demand, pondage conditions, and available stream flow.

The accompanying diagram (Fig. 7), which is the load curve of a large power system for the maximum demand week of December, shows clearly what is meant by firm capacity of a hydro plant. The system for which the load curve is presented had a peak load in 1926 of 1,150,000 kw. In the system there are hydro plants, with ample pondage, having an installation of 250,000 kw. During a minimum-flow December week, there is available at these hydro plants 4,050,000 kw-hr. The shaded area shows the load that could have been carried by this hydro with the energy available. It indicates that the firm capacity of these plants in that week was 241,500 kw., which is within 8500 kw. of the installed capacity. It will be noted that although the hydro plant during such a week of maximum demand and minimum available energy would have been operating on a load factor of only 10 per cent, the hydro was supplying 21 per cent of the required capacity. An analysis of other weeks showed that the week of maximum demand provided (as is usually the case) the most severe criterion for determining the load which the hydro plants could be relied on to carry.

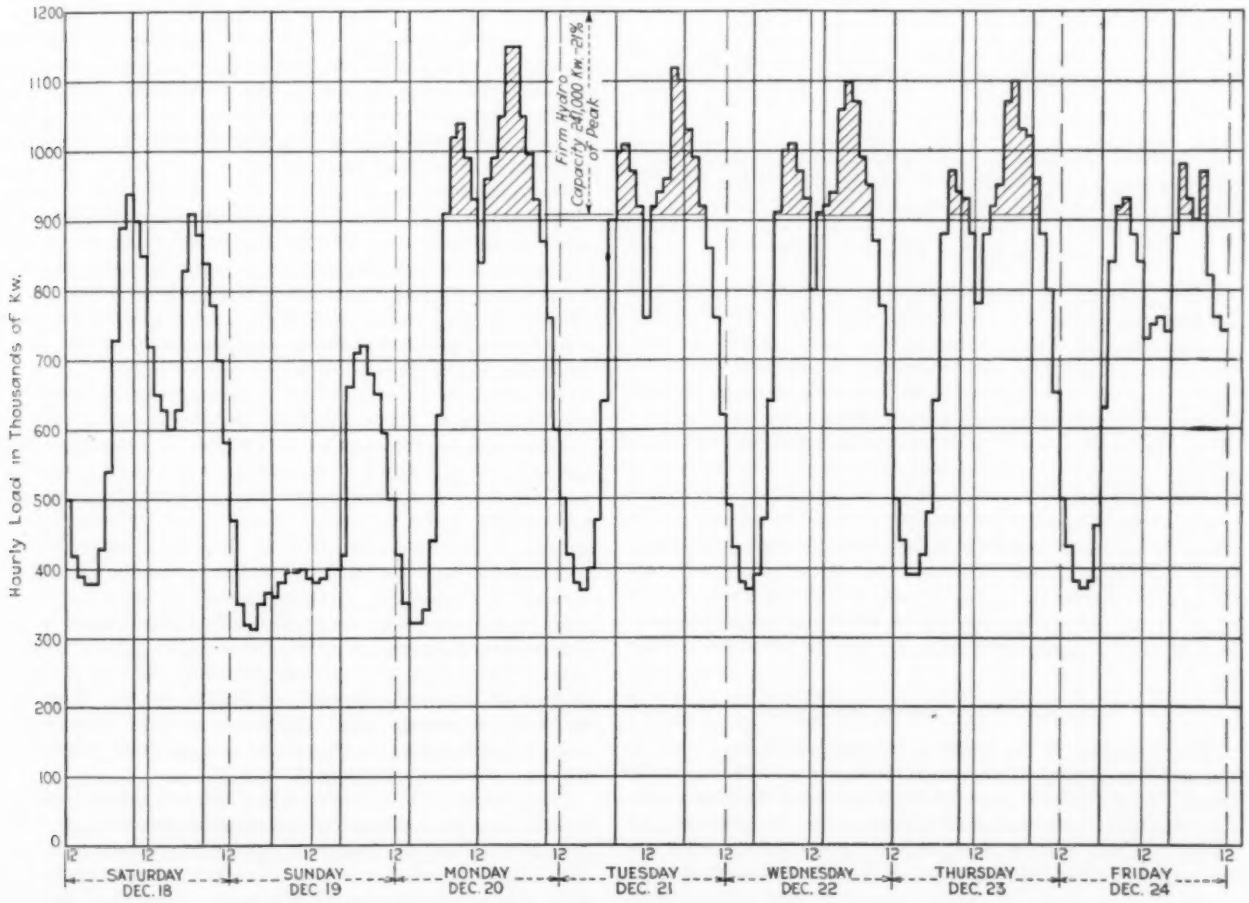

Fig. 7 Load Curve for the Peak Week of 1926 of a Large Power System
(Kw-hr. for week, 122,000,000; hydro kw-hr. available, 4,050,000.)

Steam Plant Costs as a Yardstick for Hydro

In order to measure the relative values of a hydro plant for serving any part of the load curve, it is necessary to use steam as a yardstick. Grossly erroneous conclusions may be drawn by using either average or increment costs. The total annual cost of a steam plant may be divided into the following factors:

(1) Fixed charges in dollars per kilowatt per year.

(2) Fixed component of operating in dollars per kilowatt per year. This is a fixed annual item for any given plant regardless of peak carried or energy turned out.

(3) Peak prepared-for cost, dollars per kilowatt per month. This cost varies with the peak prepared for and carried for each month.

(4) Increment cost of energy per kilowatt-hour. This is a constant unit cost regardless of quantity of energy.

For preliminary studies, items (1), (2), and (3) may be computed on an annual basis and called the annual unit capacity cost of steam. For a 400-lb. steam plant having a capital cost of $100 per kilowatt, fixed charges of 12 per cent, and a $4 coal cost, the annual unit capacity cost may be $16 per kilowatt per year, made up of $12 fixed charges and $4 for the sum of items (2) and (3), and increment cost of energy 2.4 mills per kilowatt-hour.

Thus, assuming, for simplicity, no transmission differential against hydro, if a 100,000-kw. hydro project is being considered with a firm capacity of 80,000 kw. and a utilizable energy production of 360,000,000 kw-hr. per average year, the comparative annual value would be:

(From firm capacity) 80,000 × $16	$1,280,000
(From energy) 360,000,000 kw-hr. at 2.4 mills	864,000
Hydro comparative annual value	$2,144,000

If the total annual cost of hydro were 10 per cent, this would justify a maximum investment of $21,440,000 for the 100,000-kw. hydro plant having a firm capacity of 80,000 kw.

Importance of Firm Capacity

From the tentative set-up given, the very great importance of the firm capacity of the hydro plant is evident. Thus, it is at once evident that if the determined firm capacity had been only 40,000 kw., the justifiable expenditure would have been much less. Firm capacity is dependent on stream flow, pondage, and the load curve. If a hydro plant has ample pondage, the firm capacity will increase with the growth of the system-load curve and gradually approach the installed capacity. Although this factor is of the utmost importance in connection with considering the economic advisability of hydro projects, it does not receive the attention which it requires, for certainly the hydro is only fully useful in so far as it can do the work which a steam plant might do. There are of course collateral advantages in having some hydro power in any power company system, which the author has mentioned, but it is often better not to attempt to give these a dollar value.

Proportion of Steam and Hydro

The proportion of steam and hydro capacity in any given system which is economically advisable is dependent on so many different factors that each particular case requires a thorough analysis. Based on a number of investigations, it may, however, be stated that in a number of systems in the eastern United States it is economically advantageous to serve from 16 to 40 per cent of the total load of the system from peak-load hydro plants, the remainder of the load being served by steam plants and base-load hydro plants like Niagara. The variation in the percentages is caused by such factors as shape of load curve, capital cost of hydro projects, stream flow available, cost of storage, availability and extent of pondage, additional transmission required for hydro, etc.

Depreciation and Obsolescence

One statement made by the author should most certainly be challenged. Not many engineers will agree with the statement that 10 per cent per year is a proper obsolescence and depreciation charge against steam plants. It is only relatively true to say that a steam plant ten years old is obsolete. Such a plant still has earning capacity, but its function is altered. Instead of operating on the base of the load, as it did when first built, it is now either held in reserve or operated over short-time peaks. In this function, however, it obviates the necessity of additional capital expenditures for another new plant at the rate of perhaps $100 per kilowatt and hence cannot be considered obsolete until such time as it would pay to scrap it. This is a much debated subject, but to the writer it does not seem logical to include obsolescence as such in economic set-ups of this nature. We really do not have to worry about obsolescence at all—it takes care of itself. This is for the reason that, if we are going to build a new plant to fully supersede an old plant, the net earnings for the new plant must be great enough to carry not only the investment in the new plant, but also the unamortized investment in the old plant. In other words, to build a new steam plant to supersede an old one, the annual fixed charges plus operation and maintenance costs on the new plant should be less than mere operation and maintenance costs on the old plant.

It is believed that 3.5 to 5 per cent is ample allowance for depreciation on steam plants. Depreciation on hydro plants will vary with the percentage of the total investment in dams and reservoirs from 0.5 per cent to 1.5 per cent. In general, there will be a differential in favor of hydro plants on the score of depreciation of from 2 to 3 per cent.

Nelson E. Funk.[7] The writer is a firm believer in the author's principal conclusion—namely, that where economically practicable hydro-plant sites are available, a system can generate power cheaper by combining steam and hydro plants than by utilizing either one to the exclusion of the other. The recent construction of the Conowingo Plant is sufficient evidence of the official policy of our company in the same direction.

However, it is felt that the author's comparison of steam and hydro stations, in many of its details, should not be allowed to stand without criticism as an example of economic study. Among the minor points of comparison which seem unsound is that regarding financing. Certainly, fundamental economics would dictate that if the overall kilowatt-hour cost was the same with either of two proposed systems, the one requiring the least investment of capital would be preferred. Likewise, the author's criticism of the reliability of steam plants is not well taken. He states that hydro plants are mechanically $2^1/_2$ to 6 times as reliable as steam plants, when in reality this is the ratio of the outage times. The true comparison of the reliability of steam and hydro plants is in the service demand availability factors, taken from the N.E.L.A. reports which the author quotes; these factors being for hydro units 98.40 per cent and for steam units 95.16 per cent. The comparison is obvious.

The portions of the author's paper which it is believed are most open to question are those in which the statements are made, without proof and as if they were generally accepted facts, that the present economic life of a steam turbine is approximately 4.6 years, that annual charges for retirement should be of the order of 10 per cent on steam-plant equipment, and that few steam plants 10 years old are not obsolete.

In the Richmond Station of the Philadelphia Electric Company, two turbines installed in 1925, and hence four years old at the present date, are the first-line units of the company's system. In Chester and Delaware Stations, which are of economy slightly less than that of Richmond Station, the units have been installed at various times from five to eleven years ago; while Schuylkill Station, with units installed from twelve to fifteen years ago, still remains in operation and has resisted every effort to justify its retirement. This record indicates the fallacy of the author's statement of the short economic life of steam turbines. As a matter of fact, the very rapid early development of steam-station efficiency to which the author refers as

[7] Vice-President in Charge of Engineering, Philadelphia Electric Company, Philadelphia, Pa. Mem. A.S.M.E.

proof of the short economic life of steam units is really evidence that the units installed within the last fifteen years are not likely to be retired from the standpoint of obsolescence alone for many years. Hence, the physical life of the units becomes the controlling factor in determining the suitable rate of annual retirement charge, and this indicates that 3.5 per cent is a much more logical rate than 10 per cent, although even the latter figure would be insufficient if the author's term of useful life were correct.

Regardless of the accounting methods which may be used in regard to the annual retirement charge, and whether or not the existing investment has been written off, the actual comparison which must be made when the retirement of existing capacity is being considered is that the existing capacity represents money which has already been invested and which must be thrown away if the equipment is retired, while the new investment represents additional money which must be found and upon which fixed charges must be paid.

The truly economic utilization of existing capacity is to retain it in service during its physical life, assigning the peak of the load to the plant of highest cost and the base to that of lowest cost, unless new capacity can be installed of a total cost (fixed plus operating) per kilowatt-hour less than the operating expense alone of the existing capacity.

This method of utilization results in pushing any given plant each year higher into the peak of the load so that its capacity is fully utilized with a smaller and smaller output of kilowatt-hours. Hence, the total cost of the plant (fixed plus operating) likewise decreases from year to year, and its effect upon the total cost of the growing system load becomes smaller and smaller. It will be found that this method of utilization of existing capacity with reasonable annual retirement charges will result in a materially lower cost of generation per kilowatt-hour than premature retirement of existing capacity, simply because new capacity can be installed to operate more cheaply.

Author's Closure

It is pleasing to note the amount and the competence of the discussion that has followed this paper. As indicated in the paper itself, it could only be an outline, as evidenced by the several thousand pages of current literature on the subject that were read during the time of its preparation. No paper of reasonable length could summarize all this without appearing to be a summary of accepted facts. It could only be a summary representing the author's interpretation of existing data in the light of his own experience. The author believes the criticism on this point to be well taken.

The influence of increasing load on capital expenditure has a marked effect on the cost of power, particularly on the factor of obsolescence and depreciation. It has had the effect of minimizing the importance of obsolescence or depreciation. This particular question of obsolescence seems to have drawn more discussion than any other. This is a factor that can be judged somewhat from experience, but at present can only be approximately determined. Certainly no percentage can be arrived at that will apply to all conditions. It is also evident that the percentage range is rather wide, as indicated by the discussion.

It does seem plain to the author, however, that the percentage usually used for obsolescence of steam plants is too low considering the rapid advance of the art and the vital effect of load factor on cost of steam power. Several outstanding steam engineers seem to recognize this. The author has at hand the statement of one of the steam-turbine manufacturers in this country stating that "the present economic life of a steam turbine is about 40,000 hours" (about 5.6 working years). Also he would quote from the paper, "Factors Affecting Power Cost," by C. F. Hirshfeld, appearing in *Mechanical Engineering* in the issue of November, 1929 (this was after the author's paper had been submitted, but before it was published):

> It is not so long ago that power-plant equipment was assumed to have a life of at least 20 years and power-plant buildings a life of 25 or 30 years. Such values are conservative when one considers only the operating possibility. However, when one considers the operating probability, far different figures frequently present themselves. It is not that the apparatus is worn out, but that it is less desirable and useful than before because of size, thermal economy, personnel requirements, location, flexibility, or what not. The graphs of Figs. 2 and 3, which give the histories of outputs of different units in two typical stations, show very well what happens when plants are built serially or units are installed serially. Each unit, in general, reaches a peak of production and then drops off in favor of more modern units. It is obvious that while 20 or more years of use may be assumed as feasible, about *five to seven years* of heavy-duty life represents a good average if these graphs are typical. And they are typical of a great many actual cases. It is such uncertainties as are indicated by these graphs that make many executives "play safe" when it comes to estimating probable useful as against usable life.

There are to be sure, as indicated by Mr. Nelson E. Funk, important instances where steam turbines operate against the base of the system load for longer periods. The addition of hydro power to a system on account of its allocation to the peak of the load has the effect of prolonging the economic life of existing steam turbine plants on that system.

It would not seem that the rapid development of fuel-burning plant efficiencies in the past would argue against the continuance of their rapid development in the future, inasmuch as the overall efficiency now is not much over 26 per cent.

The relative reliability, or, as the author has taken it, the relative *unreliability* of steam and hydro plants, affects the reserve capacity required. This reserve capacity is on account of generating units being off the line; so a comparison of outages was chosen as emphasizing more clearly the relative effect upon required reserve capacity than would operating percentages. In other words, the shortcomings of the two methods of generation were purposely chosen since attention to them represents progress. The discussion states, "Certainly fundamental economics would indicate that if the overall kilowatt-hour cost was the same with either of two proposed systems, the one requiring the least investment of capital would be preferred." This may be taken as a fundamental principle of economics, but in the particular case pointed out in the paper, making the larger investment does not in any way penalize the consumer or the public, but does have the effect of rewarding good management and enterprise by increasing this part of the rate base.

HYD-52-7a

The Flow of Fluids Through Orifices in Six-Inch Pipes

By S. R. BEITLER[1] and PAUL BUCHER,[2] COLUMBUS, OHIO

In this paper the authors tell of work done in the calibration of orifices and a nozzle in a six-inch pipe line using water and steam as the fluids to be metered. Two series of orifices were tested. One series included concentric orifices with from 15 per cent to 84 per cent diameter ratio. The second series included concentric orifices with from 64 per cent to 87 per cent diameter ratio. The nozzle tested was a one-flow type with 58 per cent diameter ratio.

WITH the improvement in efficiency of power plants and the necessity for a more accurate determination of the various losses, there has come a demand for increased accuracy in the meters used. A few years ago if a meter was accurate to about 3 per cent, it was considered very good, but today the users of meters are demanding accuracies of 1 per cent or less, and so an increased knowledge of the things affecting the accuracy of the meter is of great importance.

Most of the meters used for this type of work are what are known as the inferential-head type which depend upon measuring the rate of flow by determining the pressure drop across some "primary element" placed in the pipe, through which the fluid is flowing. The "primary elements" most commonly used are the venturi tube, flow nozzle, and thin-plate orifice. The theory upon which these primary elements operate should be familiar to all engineers and will not be discussed here.[3] The "coefficient of discharge" of these elements is of great importance, and so far as is known now can only be determined experimentally.

While a great deal of work has been done in determining the coefficients of discharge of the various primary elements for different fluids, there are very few published results of accurate determinations of these coefficients, especially for steam as the fluid is measured.

Because of this fact, it was suggested to the council of the Engineering Experiment Station of the Ohio State University that the equipment of the mechanical-engineering laboratory could well be used in attempting to determine some facts about the flow of steam, water, and possibly air through orifices and nozzles in pipe lines

Inasmuch as the Bailey Meter Company of Cleveland, Ohio, was intensely interested in this subject, the matter was taken up with its engineers, and they agreed to assist with the project. They have supplied all of the material, such as orifices, nozzles, special sections of pipe, and other apparatus; have granted money for the payment of observers; have given the benefit of their advice and experience whenever needed; and have loaned to the experiment station the services of R. L. Galley, one of their junior engineers, to assist in the work on the project. They have also supplied the data taken for the calibration of these orifices and nozzles with water, which had been previously determined in connection with their private research.

It is desired especially to express appreciation of the help and advice of R. E. Sprenkle and J. C. Albright, of the Bailey Meter Company, and of Professors F. W. Marquis and Horace Judd, of the Department of Mechanical Engineering of the Ohio State University, who assisted in solving some of the difficult problems which arose in the course of the work.

Scope of Investigation

This report covers the work done in the calibration of orifices, and a nozzle in a 6-in. pipe line using water and steam as the fluid

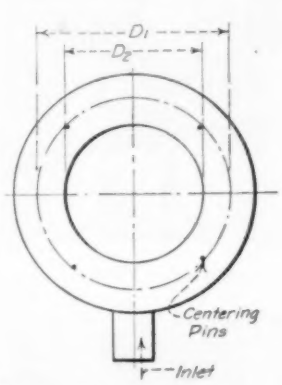

Fig. 1 Concentric Orifice

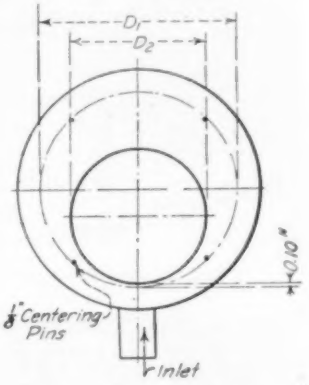

Fig. 2 Eccentric Orifice

to be metered. It is thought that the results which have been achieved so far warrant their publication although more data are continually being gathered on this subject, so that this may be considered as a progress report.

Two series of orifices have been tested, one a series of concentric orifices running from 15 per cent to 84 per cent diameter ratio, and another series of eccentric orifices varying from 64 per cent to 87 per cent diameter ratio, and a third set of one flow nozzle of 58 per cent diameter ratio. Most of the orifices were calibrated using both water and steam, but the nozzle was calibrated using steam only.

The original scope of the investigation called for the use of both water and steam with all orifices and with four flow nozzles, but it was found that the size of condensing and superheating equipment limited the capacity for steam so that it was not possible to calibrate the larger size orifices and flow nozzles using steam.

The continuation of the work is being carried on using a 3-in. line, which will make possible the use of a wide variety of orifices and nozzles, up to the largest practical diameter ratio.

The orifices and nozzle were calibrated using both water and steam. For steam the upstream pressure was 5 lb. per sq. in. gage pressure, 50 lb. per sq. in. gage pressure, and 100 lb. per sq. in. gage pressure, and from 80–245 deg. fahr. of superheat. The pipe-line velocities for water varied from 9.3 to 1042 ft. per min., and for steam at 65 lb. abs. from 346 to 7430 ft. per min. In all there were 101 tests using water, 26 tests using steam at 115 lb.

[3] For a complete discussion of this, see Part 1 of the report of the A.S.M.E. Special Research Committee on Fluid Meters, 1927.

Contributed by the Special Research Committee on Fluid Meters and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers. For discussion and authors' closure, see pp. 123–135.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

abs. pressure, 149 tests at 65 lb. per sq. in. abs. pressure, 20 tests at 20 lb. per sq. in. abs. pressure on orifices, and 6 tests at 65 lb. per sq. in. abs. pressure using a flow nozzle, making a total of 302 tests. The results of some of these tests, however, are not considered as accurate for reasons which will be discussed later.

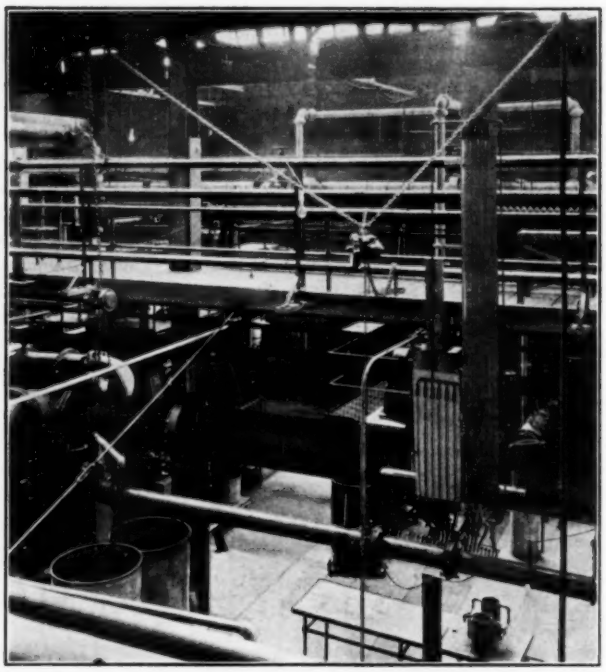

FIG. 3 PIPE LINE AND MANOMETER FOR WATER

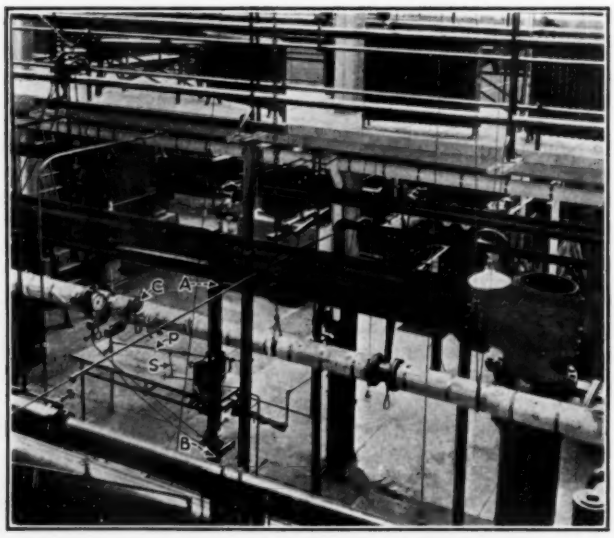

FIG. 4 PIPE LINE AND MANOMETER FOR STEAM

APPARATUS

The general shapes of the orifices used are shown in Figs. 1 and 2. These were made of Monel metal plate, and were carefully bored to the required diameter. Most of these plates were 0.039 in. thick except one plate of 0.124 in. thickness which was used for the smaller diameter ratio orifices for steam. This orifice was originally approximately 15 per cent diameter ratio, but was rebored as needed until the final ratio was 45 per cent. Also, one 50 per cent orifice for steam was cut from plate 0.061 in. thick. These thick plates were beveled on the downstream side to $^1/_{32}$ in. thickness at the orifice, which gave a square edge on the upstream side.

The orifice plates were located in the pipe by means of centering pins riveted to the plate and projecting from the upstream side of the plate. These pins were located so as to place the concentric orifices in the center of the upstream section of pipe, while the eccentric orifices were located with the edge of the orifice $^1/_{10}$

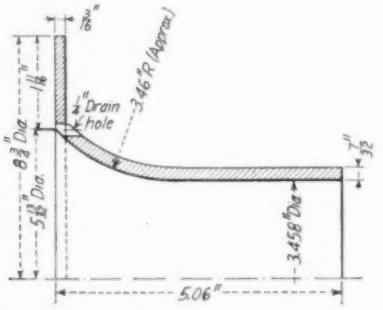

FIG. 5 HALF SECTION OF FLOW NOZZLE

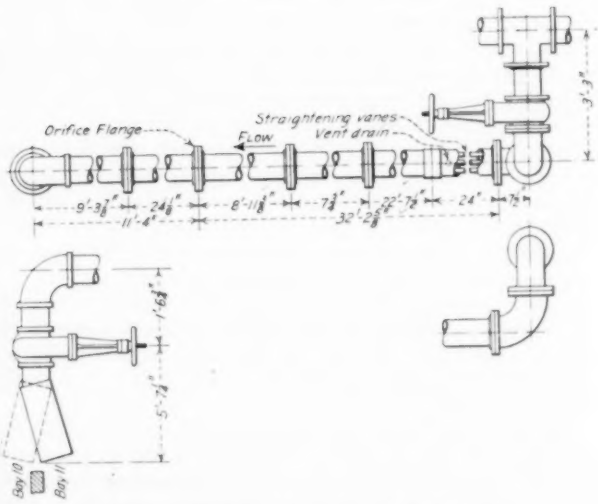

FIG. 6 LAYOUT OF TEST LINE FOR WATER

in. from the side of the pipe as shown in Fig. 2. The dimensions of all of the orifices used are given in Table 7.

Fig. 5 shows the flow nozzle tested. This is a standard flow nozzle as manufactured by the Bailey Meter Company. It was made of steel, cadmium plated, and was accurately bored to diameter before plating. This boring is done after the flanges have been turned up true, and the nozzle is reversed and mounted on a face plate. This produces a nozzle which is cylindrical on the outlet end with the flange straight and round.

The orifices and nozzles were mounted between the flanges of the two special sections of pipe shown in the illustrations Figs. 3, 4, and 6. The upstream section consisted of a piece of 6-in. standard-weight pipe 8 ft. $11^3/_8$ in. long. Pressure connections were made in this section at the points shown on Figs. 6, 7, and 8 by drilling and tapping for nipples of $^1/_8$-in. brass pipe. After the nipples were screwed into the pipe, the inside ends were carefully filed and scraped until they coincided with the inside wall of the pipe, and the edges of the holes were very slightly rounded.

The downstream section was made also of 6-in. standard pipe with pressure taps of the same type. The location of these is

also shown in Figs. 6, 7, and 8, and it will be seen that these connections were slightly staggered along the pipe. This was necessary in order to secure pressure connections at each $^1/_{10}$ diameter so that the location of the *vena contracta* could be accurately determined.

Vents and drains were provided as shown on Figs. 6 and 8. The vents were used only in starting, in order to get the air out of the line, while the drains were used to drain the pipe in order

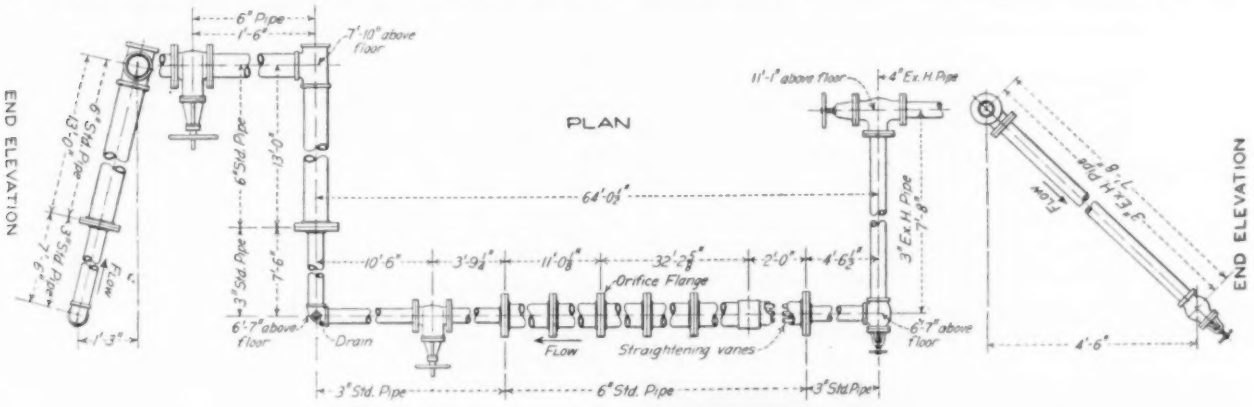

FIG. 7 LAYOUT OF TEST LINE FOR STEAM

to change orifices. A brass thermometer well was screwed into the pipe as shown. The temperature of the water was secured from an ordinary calibrated mercury thermometer placed in this well.

For steam the thermometer wells and drains were arranged as shown in Figs. 7 and 9. The thermometer wells were of brass of the finned wall type as recommended by the A.S.M.E. Code on

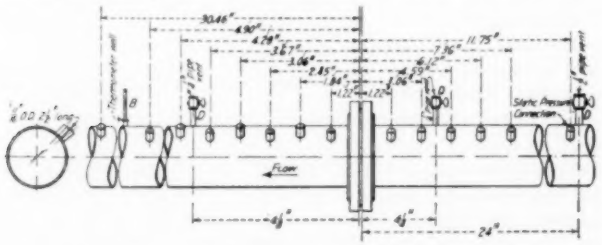

FIG. 8 DETAILS OF PIPE CONNECTIONS FOR WATER

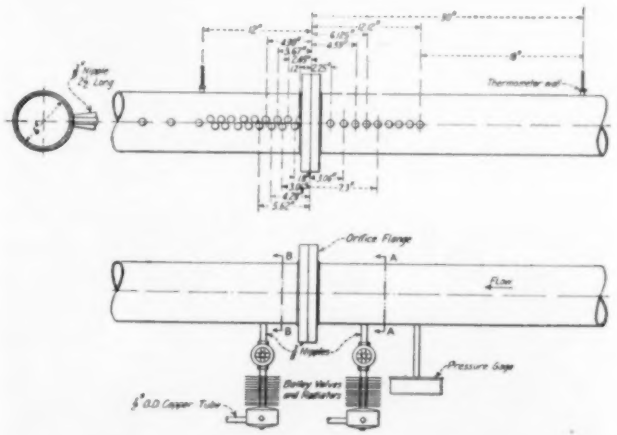

FIG. 9 DETAILS OF PIPE CONNECTIONS FOR STEAM

Instruments and Apparatus. While the thermometer placed at five diameters upstream was used for most of the runs, for some of the latter runs the one at 30 diameters was used, and for a few runs both of these were used in order to determine the temperature drop between the two positions. The drain was placed in the pipe to remove the condensation which collected in the pipe when warming up the line.

The location and general arrangement of these sections are shown in Figs. 6 and 8. It will be noted that for the 6-in. pipe, the pipe was used which gave the same arrangement for pressure connections for both steam and water. The upstream section was of such length as to give about 70 diameters of straight pipe upstream from the orifice, and the straightening vanes as shown on the drawings were put in to insure straight-line flow conditions. It was felt that this arrangement would give as nearly as possible parallel and smooth flow at the orifice section.

For water the inlet was connected to the laboratory service line by means of the valves and fittings as shown in Fig. 6. Water for calibration purposes was supplied from a 6-in. centrifugal pump having a capacity of about 1250 gal. per min., and from a 6-in. duplex pump of about 1500 gal. per min. capacity. The duplex pump was never used alone, but was used at times when the amount of water needed was beyond the capacity of the centrifugal pump. The centrifugal pump was steam-turbine driven, and was operated on a speed governor which kept a relatively constant pressure for any given capacity, while the duplex pump was operated on a pressure governor which gave a constant pressure condition so that for any one test run, the flow was fairly constant. The quantity of water used was controlled by the pump discharge valves.

When steam was used the inlet of the line was connected to the laboratory superheated steam header. The steam was generated in the University power house, and was conveyed to the laboratory through pipes located in tunnels. The steam conditions at the power house are about 185 lb. gage pressure and 130 deg. of superheat, but the pressure is reduced before it reaches the laboratory to about 140 lb. gage, while the temperature or quality of steam varies a great deal depending upon the quantity of steam being used. The steam was piped through a separate gas-fired superheater, and then into the superheat header. With this arrangement it was possible to supply steam at a fairly constant pressure and temperature to the orifice line for any particular run, so that conditions would not change appreciably during any run. The quantity of steam flowing was controlled by the 3-in. angle valve shown in Fig. 7.

The entire pipe line, except for a few fittings, and the section just before entering the condenser, was lagged by covering with 85 per cent magnesia pipe covering of standard thickness.

The quantity of water was measured either by weighing or by volumetric measurement. The arrangement for weighing the water is shown in Fig. 3. A piece of 6-in. pipe about 8 ft. 9 in. long was attached to the downstream orifice section, and a 6-in. elbow was placed on the end of this with the outlet turned up. The outlet of the elbow was bushed down to 2 in. size and a 2-in. valve connected to the bushing by a nipple. This valve also served to control the pressure in the pipe. The piping from the valve was arranged as shown in Fig. 3 so that it was possible to shift the discharge into either of the two weighing tanks shown

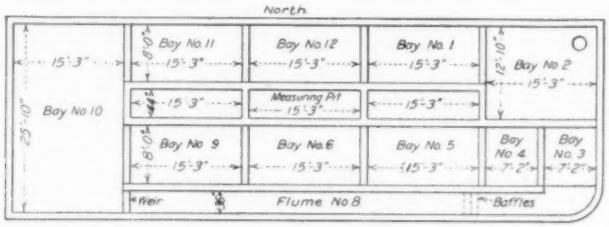

FIG. 10 ARRANGEMENT OF CONCRETE TANKS BELOW THE FLOOR OF THE LABORATORY

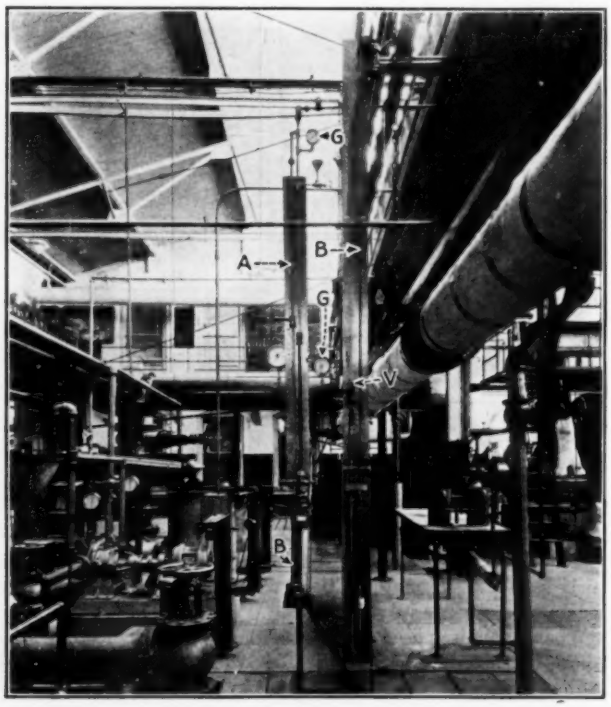

FIG. 11 MANOMETERS USED FOR DIFFERENTIAL AND STATIC PRESSURES OF STEAM

below this pipe. These tanks were of about 1200 lb. capacity and were set on platform scales. They were fitted with $2^1/_2$-in. quick-opening valves. This arrangement was used for orifices with diameter ratios from 15 to 35 per cent.

The volumetric method was used to determine the quantities passed through the larger orifices. For measurement, one of the cisterns or bays of the laboratory was used. These are concrete tanks below the floor of the laboratory arranged as shown in Fig. 10. For this work, bay No. 11 was used as a measuring bay and bay No. 2 was used as a suction bay for the pump. These bays are connected to $^3/_4$-in. gage glasses in the measuring pit in the center of the laboratory by 2-in. pipes, so that the level of the water in the bay can be read on a scale placed behind the gage glass. This scale is made of wood with a cross-section of about 2 in. × 4 in., and is kept well painted to prevent moisture from changing the length of the scale. The scale itself, reading in feet, tenths, and hundredths, is laid off directly on the white painted surface. The volume present in the bay for any gage reading is determined by calibration, and is read from a calibration chart.

When measuring larger quantities of water, the pipe was arranged as shown in Fig. 6 with a deflector pipe below the 6-in. gage valve. The deflector was arranged so that it could discharge the water either to the measuring bay or into a waste bay which was connected to the suction bay. By shifting this pipe quickly, it was possible to control accurately the lengths of test runs. The pressure in the pipe was regulated by means of the 6-in. valve.

The steam discharged by the orifices and nozzles was conveyed to a surface condenser through the piping indicated in Fig. 4. A valve was properly placed to control the pressure in the line. The condenser used was an Admiralty type of surface condenser with a cooling surface of approximately 465 sq. ft. It is fitted with a wet air pump and a circulating pump of the reciprocating type driven by a central steam cylinder. The cooling water was obtained from an outdoor reservoir, and was returned to the reservoir for cooling. The discharge of the condensate pump was piped to two tanks placed on calibrated scales of 1200 lb. capacity through a three-way cock and weighed. The cock was arranged so that the stream of condensate could be shifted from one tank to another quickly.

FIG. 12 DIFFERENTIAL HEAD MANOMETERS FOR STEAM

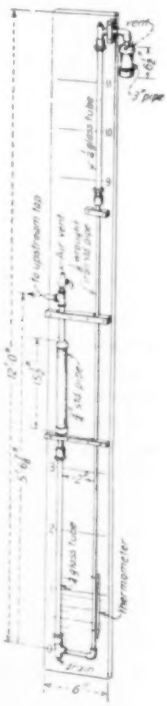

FIG. 13 STATIC PRESSURE MANOMETER FOR STEAM

The various pressure measuring devices used during the water tests may be seen in Fig. 3. The differential head across the orifice was measured by the multiple, inverted manometer shown at the right side of the illustration. This manometer consisted of four 10-ft. lengths of $^5/_8$-in. glass tubing connected to the nipples above the orifice, and six $2^1/_2$-ft. lengths connected below the orifice. The tops of these tubes were manifolded, and the manifolds were connected together by $^3/_8$-in. pipe. A $^1/_4$-in. air line was attached to the manifold at the top of the 10-ft. tubes for supplying air under sufficient pressure to balance the water pressure in the pipe. The valves in this air line were located at a convenient height, and were arranged so that the air pressure could be varied as desired, and thus the level of the water in the two sets of tubes could be set at any convenient position.

The glass tubes were connected to the nipples on the pipe by means of pieces of rubber tubing or garden hose, and pinch cocks were provided on the hose for throttling. The pipe was turned

so that the nipples were at an angle of about 45 deg. from the horizontal, and the tubes were placed above these so that the entire system was self-venting.

Thermometers were placed in the tubes as shown in Fig. 3. These were arranged at heights of 2 ft., 4 ft., and 9 ft. in the upstream tubes, and at about zero in the downstream tubes. These were used to determine the density of the water in the tubes.

Scales were laid off on the boards behind the tubes as shown. These were graduated in feet and hundredths, and the zeros were carefully leveled. The scale behind the upstream tubes was laid off directly on the board, and the board was then coated with shellac to prevent any appreciable change in length due to atmospheric conditions. The downstream scale was made of paper securely fastened to the boards. While this scale was subject to shrinkage, the customary method of operation was to adjust the

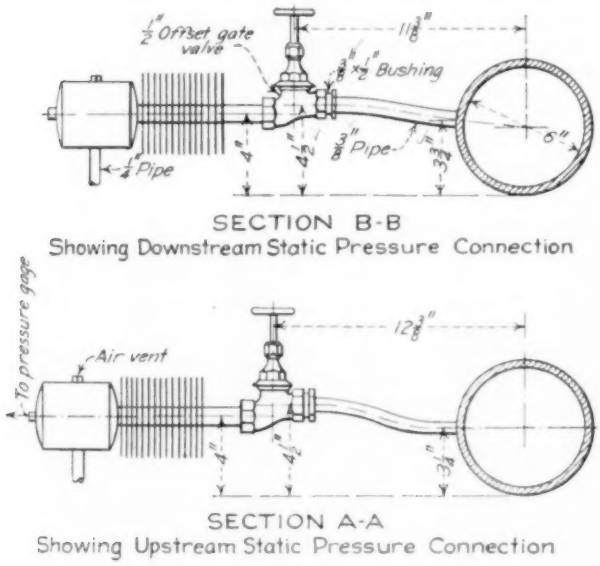

FIG. 14 DETAILS OF RADIATOR CONNECTIONS

height of the water in the tubes so that the downstream reading was near zero so that any shrinkage was negligible. With this arrangement of manometer, it was possible to get four upstream readings and six downstream readings simultaneously, and so determine the variation of pressure along the pipe both above and below the orifice.

The mercury manometer shown below the pipe in Fig. 3 was used to determine the difference in pressure between two diameters upstream and five diameters downstream, and so determine the pressure loss. Arrangements were also made to vent air from the lines leading to this manometer. The gage shown just below the manometer tubes was used for indicating the static pressure in the pipe.

Figs. 4, 11, 12, and 13 show the arrangement of the pressure-measuring devices for steam. For measuring the differential head across the orifice the two manometers "A" and "B" (Figs. 4, 11, and 12) were used. The manometer "A" was used when the differentials to be measured were less than 5 ft. of water, while manometer "B" was used for heads greater than 5 ft. "A" was a 5-ft. inverted high-pressure water manometer. It was made from gage glass and piping as shown in Fig. 12. The top of the manometer was connected to a high-pressure air line through the two tubes shown so that it was possible to adjust the pressure in the manometer approximately to the same pressure as that within the pipe before the manometer valves were opened. The gage "G" (Fig. 11) was used to indicate the pressure in the top of the manometer. The manometer scale was laid off upon the oak supporting board, and the board was then shellacked to prevent any change due to atmospheric conditions. The bottom of the manometer was connected to the pressure connections in the pipe through $^1/_2$-in. copper tubing and radiators which will be described later. The surface of the manometer was covered with non-shatterable glass during the tests so that the observers would be protected in case of a tube failure. The manometer "B" was connected in parallel with "A" so that it could be used when the differential head was too high to be recorded on the water manometer. It was a single-leg, high-pressure mercury manometer with a scale calibrated to read in inches and tenths. With this arrangement it was possible to get reasonable accuracy of readings for heads from $^1/_2$ ft. up to about 13 ft. of water.

Figs. 7 and 14 show the arrangement of the pressure connections at the pipe. The manometer legs were connected to the radiators by $^1/_2$-in. copper tubing and compression fittings, and a $^1/_8$-in. globe valve was mounted directly below the downstream radiator. A tee was placed between the upstream radiator and the valve for a connection to the static pressure manometer. The radiators were the standard high-pressure radiator condensers used by the Bailey Meter Company. They are built up of welded steel, and are arranged as shown in Fig. 14. The reservoir serves to keep a sufficient quantity of water to fill the tubes during any slight change of head, while the fins on the steel tube serve to condense enough steam to keep the reservoirs filled with water. A vent is provided in the top of each reservoir to permit the venting of air. These vents were operated manually while warming up the apparatus. A special offset gate valve was placed at the end of the reservoir, and this was connected to the main line through a $^3/_8$-in. extra-heavy nipple screwed into the pipe. These nipples were bent so that the upstream and downstream valves and reservoirs

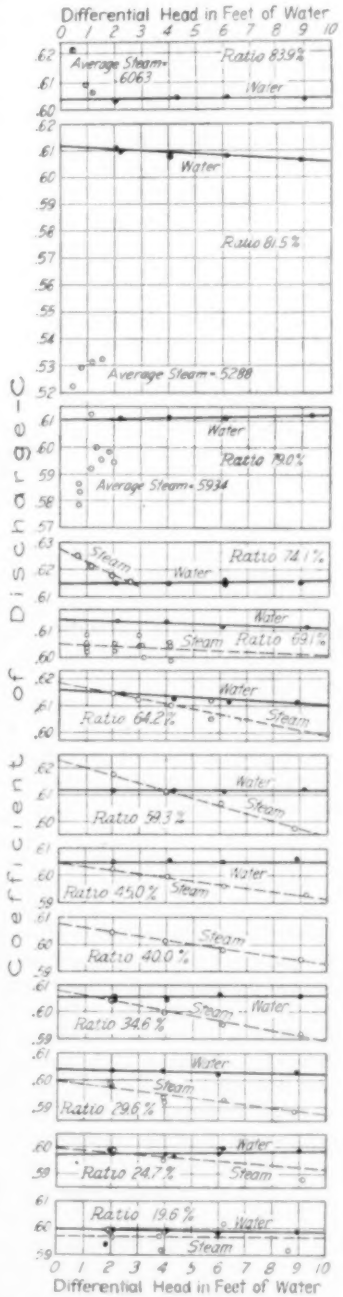

FIG. 15 VARIATION OF THE COEFFICIENT OF DISCHARGE WITH DIFFERENTIAL HEAD FOR CONCENTRIC ORIFICES

were level. This assured that as nearly as could be determined, the water head from the pipe to the manometer was the same on both upstream and downstream orifice connections. The ends of the nipples were carefully filed to give a smooth surface inside the pipe.

A plug was taken from the end of the upstream-reservoir, and a gage was connected to the reservoir to read the static pressure at the upstream connection. This gage was used for adjustment only, while the pressure during the test runs was measured by means of the mercury manometer shown in Fig. 13 and at "B" in Fig. 11. This was a two-leg mercury manometer with a range 6 ft. to 11.4 ft. of mercury corresponding to pressures 37 lb. per sq. in. to 59 lb. per sq. in. This manometer was made up of two sections of $^1/_4$-in. glass tubing mounted as shown in Fig. 13, and connected by $^1/_8$-in. pipe and fittings. A mercury reservoir made of $^1/_2$-in. pipe was mounted on the high-pressure side to prevent mercury from running into the pipe, and a trap was located at the top of the atmospheric leg to prevent any high pressure from blowing the mercury out. The piping and tube packing glands were mounted on a 1 in. × 6 in. board, and the manometer scale was laid out directly on this board. The board was then well coated with shellac. The top of the mercury reservoir was connected to the upstream radiator by $^1/_4$-in. pipe as shown at "P," Fig. 4. It was not possible to grade this line down so as to make it self-venting, and so it was graded up and a vent was placed at "V," Fig. 11, to remove any air which might gather in this line.

For measuring the lower static pressures for runs at 20 lb. absolute pressure, a tee was placed in the line between the radiator and the high-pressure manometer. This tee was connected through a valve to a standard 30-in. Merriam U-tube mercury manometer. The connection for this manometer is shown at "S," Fig. 4.

For measuring the pressure during the 115 lb. per sq. in. runs the pressure gage shown at "C," Figs. 4 and 13, was used. This was a 160-lb. Bourdon tube gage of the single-tube type connected to the pipe at two diameters upstream through a gooseneck connection.

Method of Taking Data

The method of taking the data was quite similar in all cases. For the volumetric tests with water, it was as follows: With the orifices or nozzle properly centered and bolted between flanges, the pumps were started and flow established at a rate to give the desired pressure drop across the metering element. This water was passed through the deflector pipe to the suction bay until a steady flow had been established, and all of the air eliminated from the apparatus. The level of water in the measuring bay was then read. After all of the conditions were satisfactory, at a given signal the deflector pipe was snapped to a position discharging into the measuring bay, and simultaneously two stop watches were started. Readings of head and temperatures were taken at the desired intervals throughout the run. The head was read by two observers reading simultaneously. The test run was ended by deflecting the stream of water again into the suction bay and taking the time by the stop watches. After a sufficient length of time had elapsed for surging to cease in the measuring bay, a final reading of elevation of water in the bay was taken. All readings of the bay elevation were checked by two observers. The length of the test was controlled by several factors. First, in order to get accuracy, the minimum quantity of water in the bay was limited to a depth of 4 ft. If the level of water in the bay increased more than 4 ft. in a half hour, the run was limited to 30 min. in duration. Otherwise the test ended when the measuring bay was completely filled. Observations were taken so that the minimum number of head readings was 20 while the maximum time between readings was 2 min. Temperature readings and static-pressure readings were ordinarily taken at the beginning and ending of each run.

For the weighed water test, the procedure in testing was similar to the displacement tests except that the water was run into one of the weighing tanks. At the beginning of a run the discharge was shifted into the other tank, and the two tanks were alternately filled, weighed, and emptied in the usual manner throughout the duration of the test.

When steam was used the condenser and superheater were usually started, and steam was turned into the line three or four hours before the beginning of a test. When the line was thoroughly warmed, the flow was adjusted to give approximately the desired pressure drop across the metering element, and the pressure in the pipe was adjusted to the approximate static pressure desired, and the apparatus was allowed to run at this rate for about 2 hr. so that all temperatures were brought up to a point where they would remain practically constant. While this was going on the discharge from the condensate pump was allowed to

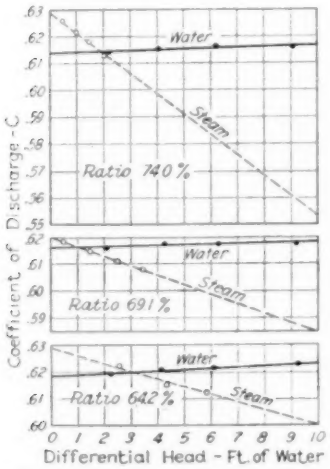

FIG. 16 VARIATION OF THE COEFFICIENT OF DISCHARGE WITH DIFFERENTIAL HEAD FOR ECCENTRIC ORIFICES

flow into the waste water trench; and while the line was warming, care was taken to eliminate all air and steam pockets from the manometer connections, and the water in the manometer tubes was allowed to cool approximately to room temperature. When the temperatures were constant, the test was started by throwing the three-way cock to discharge the condensate into one of the weighing tanks, and the time of start was noted on a reliable chronometer. Readings of head, temperatures, and pressures were taken at the desired intervals throughout the run. The differential head readings were made by two observers reading simultaneously when the water manometer was used, and by one observer when the mercury manometer was used. For runs at the 65-lb. and the 20-lb. pressures the mercury manometers were used, and were also read simultaneously by two observers. The test was ended at a certain time by shifting the condensate discharge into the waste trench again. During the runs the cans were alternately filled, weighed, and emptied as with the weighed water runs. Each run was made of sufficient length to get at least three tanks of water, the minimum amount in a tank being about 225 lb. The maximum length of run was 90 min. and the minimum (for 3000 lb. of water) was 15 min. Readings were taken of all pressures and temperatures at such intervals that the minimum number of readings was 20, and the maximum time between readings was 2 min.

CALIBRATION OF INSTRUMENTS

All instruments used were calibrated carefully.[3] The platform scales were calibrated before and after using over the entire range by means of standard weights. These weights were then checked by the Ohio Sealer of Weights and Measures, and found to be accurate within $^3/_4$ oz. in 100 lb., and the errors were found to be practically compensating.

The scales could be read to about $^1/_4$ lb., and were found to be so accurate that no correction was necessary. Care was taken at all times to keep the knife edges clean, and dirt and water off all working parts of the scales.

The measuring bay was calibrated by filling it with water. The water was weighed as it was put in, the height of the water in the bay gage glass noted, and the temperature of the water taken. The weight of water was found by using tanks on calibrated platform scales. A reading of the height of water in the bay was taken for about every 2000 lb. of water. A curve was then plotted showing the amount of water present in the bay for any gage height.

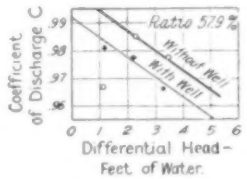

FIG. 17 VARIATION OF THE COEFFICIENT OF DISCHARGE WITH DIFFERENTIAL HEAD FOR FLOW NOZZLE

All thermometers were calibrated, the low-reading ones against a standard thermometer, and the high-reading ones by being placed in a well similar to the one in which they were used, and checked against steam temperatures.

The gages used were checked against a dead-weight gage tester. The gage tester was checked by carefully measuring the plunger diameter, and weighing the weights on a chemical balance.

All manometer scales were checked periodically against a steel tape or a steel scale while the zeros of the inverted water manometer were checked with a level at the same time. All manometers were checked for perpendicularity at frequent intervals. The mercury manometer was calibrated by comparison with a water column. The stop watches used were checked at intervals against a reliable chronometer which in turn was checked against Western Union time at intervals.

The orifice and nozzle diameters were measured carefully with inside micrometers. The diameters were measured at four places, and the averages considered as the average diameter of the opening. The nozzle diameter was measured at the outlet and also at the cylindrical portion. The diameter of the pipe was measured at the upstream pressure tap, and at a point about one-half pipe diameter downstream.

DISCUSSION OF RESULTS

Throughout these tests a serious attempt was made to install the orifices and nozzle in such a manner as to make the coefficients directly comparable to those which could be applied to actual commercial installations. The primary elements were all installed in accordance with the printed instructions of the meter manufacturer, and standard sized pressure connections were also used.

The results and some of the observed data obtained are shown in Tables 1, 2, 3, 4, and 5, and the results are also shown graphically in Figs. 15 to 21, inclusive.

Some idea of the accuracy of the testing methods used, and also some idea of the accuracy with which orifices can be used as metering elements can be gained by reference to Table 6. The first two tests of this table show how closely the value of the coefficient of discharge could be checked with water after the orifice had been removed from the pipe and reinserted at a later time. The last eight tests of this table show the same effect when steam was being used as the testing fluid. Tests for comparison have been chosen where the differential head was approximately the same since a change of head might cause a slight change of coefficient.

The greatest difference, about one-half of one per cent, shown

* No therometer well in place at 5 pipe diam.

in these results is that between S132 and S142. These were tests on a 20 per cent concentric orifice, using steam at a pressure of about 65 lb. per sq. in., but the pressure for run S132 was only about 62.1 lb. while for S142 and S144 it was 64.5 and 63.8 lb., respectively. This change in pressure would probably account for some changes in coefficient.

The six tests, 1014, 1062, 1041, 1046, 1064, and 1065, illustrate the close agreement of results when measuring the quantity of water by displacement, and when determining it by observing weight and temperature. The 25 per cent ratio concentric orifice was tested by both methods, and when tested at four foot head, a disagreement of only one part in six hundred was discovered. The 35 per cent ratio orifice was tested in a similar manner with a two-foot differential head, and the average value of the coefficient of discharge for two short weight runs was within one part in two thousand of the average value of the coefficient determined by the much longer displacement runs. The coefficients for the two displacement runs agreed with each other within one part in three thousand. These results are thought to be fairly conclusive proof that volume displacement tests of this nature when properly conducted have just as great a degree of accuracy as can be obtained from the direct weight of the water.

The curves in Figs. 15, 16, and 17 show the variation of the coefficient of discharge with differential head for the various orifices and the nozzle. These were plotted against the head in feet of water since most meters have head measuring devices which measure equal heads

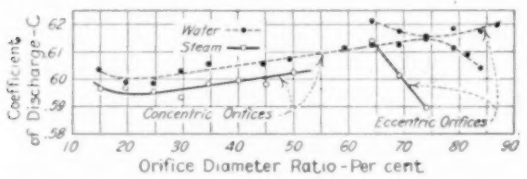

FIG. 18 VARIATION OF THE AVERAGE COEFFICIENT WITH DIAMETER RATIO FOR ALL THE ORIFICES

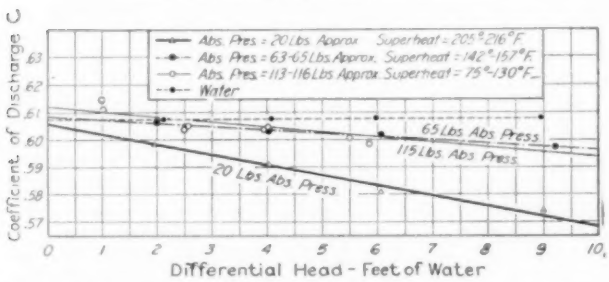

FIG. 19 VARIATION OF COEFFICIENT WITH HEAD FOR WATER AND STEAM AT VARIOUS PRESSURES USING 50 PER CENT CONCENTRIC ORIFICE

no matter what fluid is being metered, and in most of the test runs the head was actually measured in feet of water.

An inspection of the curves for the concentric orifices in Fig. 15 for water shows that they are, with the exception of the 64 per cent and 81.5 per cent diameter ratio orifices, practically horizontal, straight lines. The 64 per cent and 81.5 per cent diameter ratio coefficients of discharge seem to decrease with an increase of head. This, however, was only a tendency and was probably due to some eccentricity of installation. This peculiarity was noted with the 74 per cent and 79 per cent diameter ratio orifices which when first tested showed quite a variation of coefficient with head. When removed from the pipe and carefully inspected and reinstalled in the pipe, the variation did not appear, and the points which are plotted were determined. It seems to be apparent that if carefully installed, there were no appreciable variations in coefficient of discharge with head for a concentric orifice using water for the head ranges between two and nine feet of water.

The curves of the eccentric orifices for the tests with water seem to show that the coefficient has a tendency to increase with an increase of head. This tendency, however, is small, averaging for the three orifices tested only about 3 parts in 600 with a head differential variation of from two feet to nine feet of water. All of the curves for steam, however, except for the 19.6 per cent diameter ratio orifice show that the coefficient decreases rather rapidly with head. This is probably due to the effect of the expansion factor for steam which will be discussed later. The curves for all orifices below 70 per cent diameter ratio are practically parallel lines. The coefficients for the concentric orifices below 50 per cent diameter ratio are probably more accurate than the others as these were determined when using the "thick" orifice, and with no thermometer well placed in the pipe at five diameters upstream. It was felt that the thin orifices especially in the smaller diameter ratios might buckle when subjected to the pressures used. For this reason all results for test runs on "thin" small diameter ratio orifices were not considered accurate.

TABLE 6 COMPARISON OF COEFFICIENTS FOR ORIFICES REPLACED IN PIPE

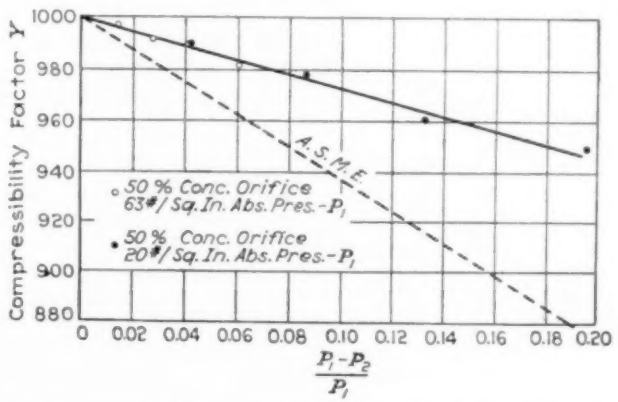

FIG. 20 GRAPH OF RATIO OF THE COEFFICIENT AS DETERMINED TO THE COEFFICIENT WITHOUT EXPANSION PLOTTED AGAINST THE RATIO OF THE PRESSURE DROP ACROSS THE ORIFICE TO THE ABSOLUTE PRESSURE UPSTREAM

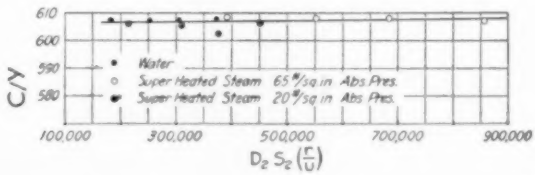

FIG. 21 GRAPH WITH VALUES OF C/Y PLOTTED AGAINST $D_2S_2\left(\frac{\gamma}{u}\right)$

The effect of a "finned" thermometer well in the pipe five pipe diameters above the orifice, upon the coefficient of discharge is not known, but it probably had some effect, and this effect would probably increase with an increase in the velocity of approach. For this reason, the absolute accuracy value of the coefficients as found for the orifices above 50 per cent diameter ratio is somewhat questionable.

Why the curve for the 20 per cent diameter ratio orifice should not be parallel to the others is not apparent, but for this orifice of small diameter the flow in the line was so small that it was difficult to maintain temperature conditions constant, especially for the low heads, and this no doubt would affect the accuracy of the coefficient.

For the larger orifices and for the one flow nozzle tested, it was impossible with the condensing equipment available to get high enough rates of flow to extend the curves far enough to make the results comparable. These points, however, have been included in the data, and the results are plotted to show that the tendency was for the coefficients for steam to fall close to those for water over the entire range of orifice sizes tested.

The data and curve for the nozzle are included only as a matter of interest, although there were not enough tests made to draw any conclusions. However, the effect of the thermometer well at five diameters upstream is shown by the higher coefficient curve obtained without the well as compared with the tests with the well inserted.

Fig. 18 shows the variation of the average coefficient for all the orifices with variation in diameter ratio. Compared with the curves published in the 1927 report of the Fluid Meters Committee, page 38, the coefficients determined for water seem to be about $1^1/_2$ per cent lower than those of curve "C" obtained by Spitzglass using air in a 6-in. pipe, though the general shape of the curve is about the same as those of Spitzglass for the 3-in. and the 6-in. pipe. The actual values of the coefficient agree very closely with those read from curve "A" obtained by Judd using water in a 5-in. pipe except for the diameter ratios above 60 per cent. Since Judd's results were based on downstream pressure readings at one-half pipe diameter below the orifice, and these are based on readings at the vena contracta, a disagreement might be expected especially at the higher values of orifice ratio.

The curve showing the variation of the coefficient for steam with orifice ratio appears to be about parallel, and about 1 per cent lower than the corresponding curve for water. This is due to the variation of the coefficient with head in the case of steam as shown in Fig. 15.

Fig. 19 shows the variation of coefficient with head for water, and for steam at 20 lb. per sq. in., at 65 lb. per sq. in., and at 115 lb. per sq. in. absolute pressure using a 50 per cent concentric orifice. All of these curves except the one for steam at 115 lb. per sq. in. seem to intersect the zero head line at the same place within the limits of accuracy of the experimental work. The curve for 115 lb. per sq. in. absolute pressure intersects the zero head line at a point about 1 per cent higher than do the others. The curve for water is practically a horizontal, straight line while those for steam at 20 and 65 lb. per sq. in. absolute pressure slope away from this, the 20-lb. curve sloping more than the 65-lb. curve. This agrees with theory as the effect of the compressibility of steam is greater for the lower absolute pressures with the same differential head. The slope of the 115-lb. line, however, lies between the 65- and 20-lb. lines. This apparent disagreement seems to throw doubt upon the accuracy of the values of the coefficient determined at 115 lb. per sq. in. For these tests the same apparatus was used for measuring everything except the static pressure. This pressure was measured by a 160-lb. pressure gage mounted two diameters upstream in place of the mercury manometer at one diameter upstream used for the other pressures. This gage was calibrated each day it was used, before and after being placed on the pipe, and so should be accurate, but the fact that it was used and that the results do not line up with the others tend to cause a belief that some inaccuracy in the pressure measurement is the cause of this error.

In Fig. 20 these tests are also used for a further study of the effect of compressibility. In it the compressibility factor Y, which is the ratio of the coefficient as determined to the coefficient without expansion, is plotted against the ratio of the pressure drop across the orifice to the absolute pressure upstream. Since the 115-lb. absolute-pressure line does not agree with the other pressure lines in Fig. 19, it was neglected in the determination of this curve. On the same sheet is plotted a curve of the calculated values of Y taken from the table, page 23, of the Fluid Meters Report. From these curves it will be seen that the values of Y determined experimentally do not check the calculated values. In getting the values for the curve the values of Y were calculated from the experimentally determined coefficients using the point of intersection of the head coefficient curve with the zero head axis as the value for the coefficient C where there was no expansion effect, and assuming that the coefficient for the orifice was constant over the head range used. The value of C for water was constant over this head range, and as water is practically incompressible this assumption should be correct. The points for both the 65 lb. per sq. in. and the 20 lb. per sq. in. absolute pressure tests fall fairly close to the same straight line, and seem to show that actual correction for compressibility is much less than the theoretical value. However, the evidence of eight runs is not enough to prove this fact, and an attempt is now being made to gather more data concerning it.

Apparently the amount of superheat had no effect on the coefficient as long as it was high enough to insure dry steam, and was constant during any run. This was true at least over the range of temperatures which was covered. An inspection of the last seven runs in Table 6 will show that a temperature difference of as much as 30 deg. fahr. had little, or no, effect on the value of the coefficient. However, any great change of temperature during a test tended to give a value of coefficient that was not

comparable since the change in temperature affected the pressure and the flow of steam a great deal.

An attempt was made to discover if it was possible to apply the viscous flow criterion to both steam and water, and to determine if this criterion would apply to orifices of different sizes. It was found that for the 50 per cent diameter ratio orifice using water and steam at 20 and 65 lb. per sq. in. absolute pressure, the curve as shown in Fig. 21 could be drawn. In this curve the values of C/Y have been plotted against $D_2S_2\left(\frac{\gamma}{u}\right)$, where D_2 is the orifice diameter in feet, S_2 the velocity of flow through the orifice in feet per second, γ the density in pounds per cubic foot, and u the absolute viscosity in foot-pound-second units of the fluid being metered. C/Y was determined by using the value of Y read from the curve plotted in Fig. 20 and the experimental values of C. The values of u were taken from the paper on the "Laws of the Similarity for Orifice and Nozzle Flows" by J. L. Hodgson, a paper presented by the committee on fluid meters at the 1928 annual meeting of the A.S.M.E.

It will be seen that all but one of the twelve points plotted fall very nearly on a straight line with the values of C/Y increasing slightly with increase of $D_2S_2\left(\frac{\gamma}{u}\right)$. Any attempt to apply this to orifices of other diameter ratios, however, gave simply a collection of points with no apparent order. This was more noticeable when the larger orifice coefficients were plotted. It appears from this study that this method of analysis can be applied only to orifices of the same diameter ratio. For any other ratio the change of the contour of the stream is enough to change the flow conditions.

As mentioned in an earlier part of this paper the Ohio State Engineering Experiment Station is carrying on this work using a three-inch test line. This will make possible a comparison between different pipe sizes, and make it possible to prove or to disprove the results of this first research, some of which are rather questionable.

This paper is submitted in the hope that the data already obtained may be of some value when applied to the art of metering fluids, and also in the hope that much interest will be aroused which will result in constructive criticism and many suggestions which will make the continuation of this research of greater value.

Appendix

Method of Calculation

The formula used for the calculation of the coefficient of discharge was the same for both water and steam and was as follows:

$$C = \frac{Q}{0.04376 A D_2^2 \sqrt{h}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where C = coefficient of discharge
Q = quantity cubic feet per second
A = correction for velocity of approach
$= \sqrt{\frac{1}{1 - r^4}}$ where r equals ratio of orifice or nozzle diameter to pipe diameter
D_2 = diameter of orifice or nozzle, inches
h = differential head in feet of fluid flowing

This was derived from the equation for a head meter for liquids as found on page 19 of the A.S.M.E. Fluid Meters Report of 1927. In using this formula Q and h were determined experimentally and D and r were determined by measurements of pipes, orifices, and nozzles.

For tests using water the differential head was measured directly in feet of water, however the temperature of the water in the tubes was different from that of the water in the pipe, and the observed differential head was corrected by use of the formula:

$$h = h_0 \frac{r_0}{r} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [2]$$

where h = actual differential head, feet
h_0 = head as read on manometer, feet
r_0 = density of water in manometer
r = density of fluid in pipe.

This formula is found on page 20 of the 1927 Fluid Meters Committee Report.

The density of the water was found from the tables of density found in Marks handbook, second edition, page 300.

The same formulas were used for the determination of the coefficients for steam. The value of the density of the steam at the upstream pressure tap, and the temperature at five diameters upstream was used as the value of r in formula [2].

This density was found from the steam tables published in Mechanical Engineering of February, 1926. The temperature of the water in the tubes was assumed to be the same as that of the surrounding air. A correction was applied for the unbalanced air column on the two sizes of the water manometer.

For some of the later tests using steam, the steam temperature was taken only at a point 30 diameters upstream. Enough tests were run previously to determine temperatures at both points, and to make possible the determination of the temperature at five diameters, and the proper correction was read from a curve.

Quantity-Rate Fluid Meters

Correlation of Coefficients and Expansion Factors, Using the Reynolds Number and Acoustic Velocity Ratio

By ED S. SMITH, JR.,[1] PROVIDENCE, R. I.

PREFACE

Critical consideration is invited to the first section of this paper which is offered as of use in preparing a revised edition of the A.S.M.E. Fluid Meter Report—Part One. In it, the venturi tube and square-edged orifice are placed upon a common basis and simple graphical methods of use are shown. This common basis is rigorously derived from the laws of flow similarity and dimensional homogeneity in the body of the paper.

The dimensionally correct "hydraulic" formula is used as the common basis in metering fluids ranging from highly viscous oils to expansible fluids (gases) with both types of meters as follows:

$$Q = CY \frac{A_1}{\sqrt{(D_1/D_2)^4 - 1}} \sqrt{2PW_1}$$

which does not involve gravitation "g" in any way. This formula is derived for the venturi tube (or nozzle) with a frictionless liquid, in which case the coefficient "C" and the expansion factor "Y" are both unity.

Flow similarity and the correction factors "C" and "Y" depend upon two dimensionless ratios: the familiar Reynolds number "$V_1D_1W_1/U_1$" and the ratio "x/n," which has been christened the "acoustic ratio" by the author since it is derived from the acoustic velocity ratio "V_1/V_a" ("x" is the ratio of the differential to inlet pressure, "n" is the specific-heat ratio, "V_1" is the fluid velocity at the inlet, "V_a" is the acoustic velocity—speed of sound in the fluid at the inlet). These ratios are used for correlating data on "C," "Y," or "CY" experimentally obtained with whatever fluids are convenient and then the correlated data are used with whatever fluid is being metered commercially.

For liquid meters, the coefficient "C" depends only on the Reynolds number including when the coefficient is substantially flat, which it generally is, except for unusually small meters or for those measuring viscous fluids such as heavy oils or hydrogen gas. For a liquid, the coefficient "C" does not depend at all upon the acoustic ratio "x/n," since there are practically no expansibility effects involved. This is also true for a gas when the differential is relatively low. Also where the differential is relatively high, exactly the same coefficient would be used for a gas as for a liquid having the same Reynolds number, or as though the gas were a liquid having the same density and viscosity. The net expansion factor "Y" corrects for all of the expansion effect which exists due to the gaseous nature of the fluid.

In the usual measurement of gaseous fluids, the coefficient "C," defined as above, is "flat" with any given meter, and so the expansion factor "Y" is the only one which varies appreciably with the rate of flow, being unity at the low rates. Thus, gaseous fluids are most simply metered in practice by using the "hydraulic" equation with the necessary correction factor "Y" for expansion, and then the expansion factor "Y" may be taken as a straight-line function of the acoustic ratio "x/n." The conditions at the inlet are used throughout to make the method universal for venturi tubes and orifices and to gain other important advantages.

An original example illustrates the relation between flow similarity, Reynolds number, and coefficient by using parallel streams of fluid following "viscous" and "inertia" resistance laws, respectively.

The paper also presents material on factors which cause departure from the theoretical flow conditions, illustrations of the flow with venturi tubes and orifices, viscosity, friction loss, and flow in pipes, as well as other related matter.

INTRODUCTION BY R. J. S. PIGOTT

Chief Engineer, Research Dept., Gulf Prod. & Pipe Line Cos., Pittsburgh, Pa., and Chairman of A.S.M.E. Special Research Committee on Fluid Meters.

WITH a view to showing the great value of this paper by Mr. Smith, the events which led up to its publication may be of interest. The Special Research Committee on Fluid Meters of The American Society of Mechanical Engineers was formed in 1915, for the purpose of establishing, if possible, a clear understanding of fluid measurement. Knowledge of various meters, their coefficients, and general behavior was incomplete and scattered. The Committee very early decided to produce a treatise on the theory and application of fluid meters which would contain all of the authoritative data available.

In the course of this work some research was undertaken on pulsating flow: the remainder of the data has become available largely without actual laboratory work by the Committee.

The first report, Part I, on theory, was published in 1923, having taken eight years to assemble. Parts II and III on application and commercial meters are now in preparation.

The work of the Committee has been the means of bringing out several important papers on the subject. The latest was a most important paper by John L. Hodgson, summarizing his long experience in the subject; the present contribution by Mr. Smith likewise represents the results of many years' work, and is another stepping stone in the establishment of reliable knowledge of fluid measurement.

Simple relations exist between the fundamental quantities involved in metering fluids. The modern science of hydrodynamics, with its use of simple dimensionless ratios and basic formulas, has largely cleared the "art of fluid measurement" of involved, and sometimes even dimensionally wrong, formulas expressing the necessarily empirical relations between pressure differential and fluid velocity. Most of the formulas of the older conventional hydraulics were based on the relation $H = V^2/2g$, and had no proper method of making corrections for appreciably viscous and expansible fluids.

[1] Hydraulic Engineer, Builders Iron Foundry. Jun. A.S.M.E.

Contributed by the Special Research Committee on Fluid Meters and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers. Previously discussed at an open meeting of the A.S.M.E. Special Research Committee on Fluid Meters, Rochester, N. Y., May 13 to 16, 1929, and subsequently presented at the World Engineering Congress, Tokyo, Japan, October 29 to November 22, 1929, as the A.S.M.E. contribution. For discussion and author's closure, see pp. 123–135.

Innumerable experiments on geometrically similar models in both ship and airplane design have confirmed the modern theory of flow similarity in which the basic dimensionally correct formula states that the resistance (or pressure differential for a quantity-rate meter) is merely proportional to the product of the square of the velocity and the density of the fluid, with the necessary empirical constant simply a function of the two dimensionless ratios, namely, the Reynolds number and the acoustic-velocity ratio.[2]

In 1919 and 1920 the author pioneered in making practical use of the Reynolds number with viscous-liquid measurements, obtaining data with one liquid and then using these data with other liquids. Now, ten years later, he has again pioneered in making practical use of the acoustic-velocity ratio (or more simply, the acoustic ratio) with expansible fluids, obtaining data with one gaseous fluid and then applying these data to other gaseous fluids. In both cases his contributions are of the useful engineering nature of "reduction to practice" of established physical laws, rather than of a purely scientific nature.

In 1919 the author made use of the Reynolds number with data on the friction loss in oil pipe lines. Although anticipated by numerous experimenters in this field, still his personal experience confirmed definitely the soundness of this method for correlating data for various fluids for flow in pipes. Later, while testing oil pumps, it became economically necessary to calibrate a venturi meter and use this to obtain instantaneous measurements of quantity rate instead of using the flow into available large cylindrical storage tanks over a considerable period of time.

The author undertook this problem for graduate research work at the University of California, and in 1920 filed a thesis progress report which correlated full-scale venturi-tube coefficients with the Reynolds number, confirming the use of this method for various liquids, and reaching a low coefficient of 0.91.

Continuation of this work on a wide variety of fluids with a geometrically similar glass model of a venturi tube showed that this method was basically correct for various sizes of meters, and a low coefficient of about 0.012 (the usual coefficient for water is about 0.990) was reached. The equation relating coefficient and Reynolds' number for the streamline régime was definitely formulated, and the relation established between the value of the coefficient and the turbulence—as defined by the Reynolds number. Also similarity of flow was observed by visual study of dye streams in the glass venturi tube and pipe over a very wide range of Reynolds' numbers.

These results, along with a practical method of metering viscous fluids, were stated in "The Oil Venturi Meter," a paper published in 1923 by The American Society of Mechanical Engineers (R-1)[3] and attention was called to the possibility of correlating the expansion correction with the acoustic-velocity ratio for metering gases. This method of metering viscous liquids has been successfully used by the author since that time and has proved reliable from his subsequent experience.

In 1924, the "Fluid Meter Report—Part One," which was issued by the A.S.M.E. Special Research Committee on Fluid Meters (R-2), presented an independent correlation of venturi-tube coefficients, for water, with the Reynolds number made by Dr. E. Buckingham, which agreed substantially with the author's 1923 correlation using data obtained on various oils, various solutions of corn syrup and water, with both model and full-scale venturi tubes.

In 1925 the author assisted (R-3) Prof. Robert L. Daugherty in correlating the coefficients for full-scale orifices, for various oils, with the Reynolds numbers from the original data, and this work again directly confirmed the use of Reynolds' numbers for this differential producer. It is thus believed that the author is among the pioneers in the "reduction to fluid-meter practice" of dimensionless ratios, as he had contact with what are believed to be the first published correlations for full-scale venturi tubes and square-edged orifices using a variety of liquids.

In the "Fluid Meter Report—Part One," the venturi-tube theory was adequately shown with the correlation of coefficient and Reynolds' number for viscous fluids, and the expansion factor for gaseous fluids was determined by the conventional "adiabatic" expansion formula, using St. Venant's equation. For orifices, however, neither the variation of coefficient with low Reynolds' numbers for viscous fluids nor the increase of the *vena contracta* with expansion of gaseous fluids was presented.

As a member of the A.S.M.E. Special Research Committee on Fluid Meters, the author has presented a tentative revision of the "Fluid Meter Report—Part One," to the Committee, and the present notes are taken chiefly from this revision. In this the venturi tube and orifice are placed on a common basis, and a practical method of using it is also shown.

The acoustic-velocity ratio has been developed and its use simplified by the author until it forms a practical basis for correlating expansion corrections for both the venturi tube and orifice for various fluids. In the past several years a number of investigators have published material which establishes confidence in the soundness of this use of the acoustic-velocity ratio for fluid meters.

The art of metering fluids is becoming of increasing importance since accurate quantity-rate meters are required for modern industrial uses and for the control of continuous processes in the manufacture of enormous quantities of highly uniform products.

Critical consideration and discussion of both the basic theory and method of practical use are invited so that the revised edition of the "Fluid Meter Report," will be accurate and of the highest usefulness.

R. J. S. PIGOTT.

Quantity-Rate Fluid Meters

INTRODUCTION

VENTURI tubes and square-edged orifices are increasingly used in commercially metering a wide range of fluids, including highly viscous liquids and expansible gases. The following notes are offered to place the common fundamental relations upon which both forms of meters depend in convenient form for general commercial use.

For commercial metering the "hydraulic" equation is convenient, that is,

$$Q_1 = CY \frac{A_1}{\sqrt{(D_1/D_2)^4 - 1}} \sqrt{2P/W_1}$$

This is originally derived for the venturi tube (or nozzle) with a frictionless and non-expansible liquid, in which case the coefficient C and expansion factor Y are both equal to unity.

Flow similarity and the combined coefficient and expansion factor depend, respectively, upon two dimensionless ratios: the Reynolds number and the acoustic-velocity ratio. For liquid

[2] The Reynolds number $= VDW/U$, and the acoustic-velocity ratio $= V/V_a$, where V = velocity of fluid, D = a linear dimension, W = density of fluid, U = viscosity of fluid, and V_a = velocity of sound in fluid. These ratios are significant of the actual state of flow, i.e., indicate truly the "flow similarity." The acoustic-velocity ratio can be more simply expressed as the acoustic ratio x/n, where x is the ratio of differential to inlet pressure and n is the specific-heat ratio.

[3] This and subsequent similar notation in the text refer to numbered references in Appendix No. 4.

meters the acoustic-velocity ratio naturally does not enter since it measures only expansion effects, and so the flow similarity and the coefficient C depend only upon the Reynolds number including when the coefficient is substantially "flat" (or constant), which it generally is, except for unusually small meters or for those measuring viscous oils.

For gaseous fluids at low differentials there is no appreciable effect of expansion, and so the Reynolds number determines the coefficient C, using the kinematic viscosity of the gas exactly as though it were for a liquid. Hydrogen gas, for example, has approximately one hundred times the kinematic viscosity of water, and so behaves similarly to a moderately viscous oil. For most gas measurement, however, the coefficient in the hydraulic formula is "flat," and the expansion effect may be corrected by a factor which depends only upon the acoustic ratio: a simplified form of the acoustic-velocity ratio.

In practice, coefficients and expansion factors may usually be determined separately and then combined as above with satisfactory accuracy, even where there are considerable departures from the "flat" coefficient and an expansion factor of unity. Fundamentally, however, the coefficient and expansion factor are interdependent, and for a rigorous treatment must be considered simultaneously; for example, say, plotting a family of "solid" curves of combined coefficients and expansion factors for various acoustic ratios against the Reynolds number.

Flow similarity in these notes refers to geometrical similarity of flow lines and velocity distribution, and is determined by the Reynolds number together with the acoustic ratio. For example, with square-edged orifices, the size of the *vena contracta* increases with either a decrease of the Reynolds number or an increase of the acoustic ratio. Also the expansion of the fluid itself is a function of the acoustic ratio, and therefore the combined correction for the expanded *vena contracta* and the fluid expansion is a function of the acoustic ratio x/n, where x is the ratio of the differential pressure to the absolute pressure at the inlet, and n is the ratio of the specific heats. The combined expansion factor Y is thus found to be a nearly straight-line function against this simple acoustic ratio x/n in the usual differential range for gaseous fluid meters, with either venturi tubes or orifices. The data presented are purely for the illustration of the use of this method.

The above use of the "hydraulic" equation with factors depending upon the dimensionless ratios noted is rigorous and also simple. The acoustic ratio x/n is practical in use and further is particularly valuable in metering one gaseous fluid, using data obtained with another gaseous fluid.

The upstream (pipe) diameter governs the character of the flow and amount of turbulence in the pipe, and this diameter has been used as a common basis throughout, making the basis universal for pipe-friction loss, venturi tubes, orifices, and pitot tubes.[4] Otherwise, for orifices, for example, the diameter of the variable and generally indeterminate *vena contracta* would have to be used to correspond strictly with the downstream (throat) diameter of the venturi tube, and there is no corresponding constriction for the pitot tube. Also the fluid conditions may be exactly known at the upstream connection, but those at the downstream connection depend also upon the shape of the differential producer, and so are generally more or less indeterminate—as is shown, in fact, by the necessity of using coefficients.

All of the relations that can be expressed using the downstream diameter as a basis can be converted to use the upstream diameter equally well, although sometimes at a partial loss of the physical significance of critical phenomena. For example, coefficients for different shapes of venturi tubes are more closely correlated using the throat diameter as the linear dimension in the Reynolds number. However, the results may then be transferred to the pipe-diameter basis for convenience in actual use.

An additional advantage of using the upstream diameter in the Reynolds number as a convenient basis appeals to any one in selecting a differential producer to produce a given differential for a known flow through a certain size of pipe, the usual case in practice. From these conditions an equivalent "effective area" can be simply found, and from its ratio to the "pipe area" the required venturi tube throat (or orifice) diameter can be simply found by referring to the relation between this ratio of areas and the ratio of the required diameter to the pipe diameter.

It is believed that one portion of these notes presents a clear and original picture of fluid flow: an example illustrating the relation between flow similarity, Reynolds' number, and coefficient by the use of parallel streams of fluid following "viscous" and "inertia" resistance laws, respectively.

The basis for the author's revision is, briefly, the "hydraulic" equation, using the coefficient and expansion factor as determined from the Reynolds number and acoustic ratio. These notes also include their derivation from fundamental theory. A discussion of other factors affecting coefficients, along with some material on related subjects, is also included.

Grateful acknowledgment is due R. J. S. Pigott, Prof. W. S. Pardoe, and J. M. Spitzglass, colleagues on the Fluid Meter Committee, to Alton C. Chick and to John L. Hodgson, of Geo. Kent, Ltd., London, outstanding authority on fluid measurement, for their direct assistance in critically discussing these notes; to the Builders Iron Foundry for their willing cooperation; also to Winslow H. Herschel and Edgar Buckingham, who generously offered pertinent references and suggestions; and finally to Prof. Robert L. Daugherty for his friendly interest over a period of years, which has assisted in making this work possible.

I—FLUID METERING IN PRACTICE

(This chapter is offered as a basis for the revision of the A.S.M.E. Fluid Meter Report—Part I)

The Hydraulic Equation

It is convenient to use the "hydraulic" formula, which assumes that the fluid is neither appreciably viscous nor expansible, with experimentally determined coefficients for the effects of viscosity and expansibility.

This hydraulic formula is

$$Q_w = CY \frac{A_1}{\sqrt{(D_1/D_2)^4 - 1}} \sqrt{2PW_1} \quad \ldots\ldots\ldots [1]$$

or

$$Q_w = CYA \sqrt{2PW_1} \quad \ldots\ldots\ldots\ldots [2]$$

in which the following notation is used:

Symbol	Dimension	Unit	Quantity
Q_w	M/T	Lb. per sec.	Mass discharge
C	....	.....	Coefficient, correcting for viscosity, as determined by data correlated with the Reynolds number

[4] The use of simple graphical methods is ideal for correlating the experimentally determined coefficient and expansion factor with the Reynolds number and acoustic ratio. There has been much confusion due to attempts, including extremely clever ones, to express empirical data by complicated formulas instead of by simple graphs, using proper scales (logarithmic, semi-logarithmic, or whatever is most suitable). In oil flow there are three distinct régimes: streamline, superturbulent, and the usual turbulent flow (hydraulic), and this condition practically forces the use of graphical methods.

Y	....	.....	Factor correcting for expansion of gaseous fluids (Y = 1.000 for liquids)
A_1	L^2	Sq. ft.	Area of inlet (pipe)
A	L^2	Sq. ft.	Effective area of section of maximum constriction
D_1	L	Ft.	Inlet diameter (pipe)
D_2	L	Ft.	Diameter of throat of venturi tube or diameter of orifice
P	M/LT^2	Poundals per sq. ft.	Differential pressure
W_1	M/L^3	Lb. per cu. ft.	Density of fluid at inlet

For convenient use, in ordinary English units,

$$Q_w = 457.2\, CYa\sqrt{hW_1} \quad \text{.....[3]}$$

in which the following notation is employed:

Symbol	Dimension	Unit	Quantity
Q_w	M/T	Lb. per hr.	Mass discharge
457.2	$M^{1/2}/T$	.....	A physical constant
C	....	.....	Coefficient correction for viscous effects, as determined by Reynolds' number
Y	....	.....	Factor correcting for expansion of gaseous fluids
a	L^2	Sq. in.	Area of venturi tube throat or orifice corrected for approach velocity
a_1	L^2	Sq. in.	Area of inlet (pipe)
a_2	L^2	Sq. in.	Area of venturi tube throat or orifice
h	L	In.	Water differential
W_1	M/L^3	Lb. per cu. ft.	Density of fluid at inlet

$$a = \frac{a_1}{\sqrt{(d_1/d_2)^4 - 1}} = a_2\sqrt{\frac{(d_1/d_2)^4}{(d_1/d_2)^4 - 1}} \quad \text{.....[4]}$$

The absolute system of mass units is quite satisfactory, since using "pounds" for the mass unit and "poundals" for the force unit (grams and dynes correspondingly in the absolute c.g.s. system) gives the discharge in familiar mass units, while the unfamiliar force unit (poundal) is replaced in practical use by the differential head h.

The Coefficient

Fig. 1 shows the relation between the coefficient C and the Reynolds number for various differential producers. It is apparent that for a velocity range of 1 to 10, which is customary in commercial metering, the coefficient is generally substantially "flat" for commercial sizes of meters, the exceptions being for unusually small pipe sizes or for fluids having high kinematic viscosity, such as heavy oils or hydrogen gas.

The Expansion Factor

Fig. 2 shows the expansion factors for use with gaseous fluids for various differential producers.[5]

The orifice expansion correction is considerably less than that for nozzles. In both cases the factor depends upon the "acoustic-velocity ratio," which may be more simply expressed as the "acoustic ratio" x/n, where x is the ratio of the differential to the inlet pressure, and n is the ratio of specific heats for constant pressure and constant volume.

Although with the venturi tube these factors are computed for frictionless adiabatic expansion, it will be found that the above equation applies nearly exactly when using the friction coefficient C and the expansion factor Y here, as above stated, for metering various gaseous fluids with the usual commercial sizes of meters.

For the orifice, the expansion factor Y, as experimentally determined, includes the effect of both the increase in the size of *vena contracta* and also the expansion of the fluid itself. This expansion correction Y for orifices is best determined from high-pressure tests (R-4) in which the coefficient C is flat, i.e., has no appreciable variation with the Reynolds number.

The relation between this flat coefficient C for square-edged orifices having flange taps and various ratios of orifice diameter to pipe diameter is shown in Fig. 3.

The expansion correction in Fig. 2 is plotted against the acoustic ratio, which basis is entirely satisfactory for commercial metering with the differentials generally used. This graph shows

[5] The computations throughout these notes have been made with a 20-in. slide rule, and this is adequate, since the data are only presented to illustrate the method.

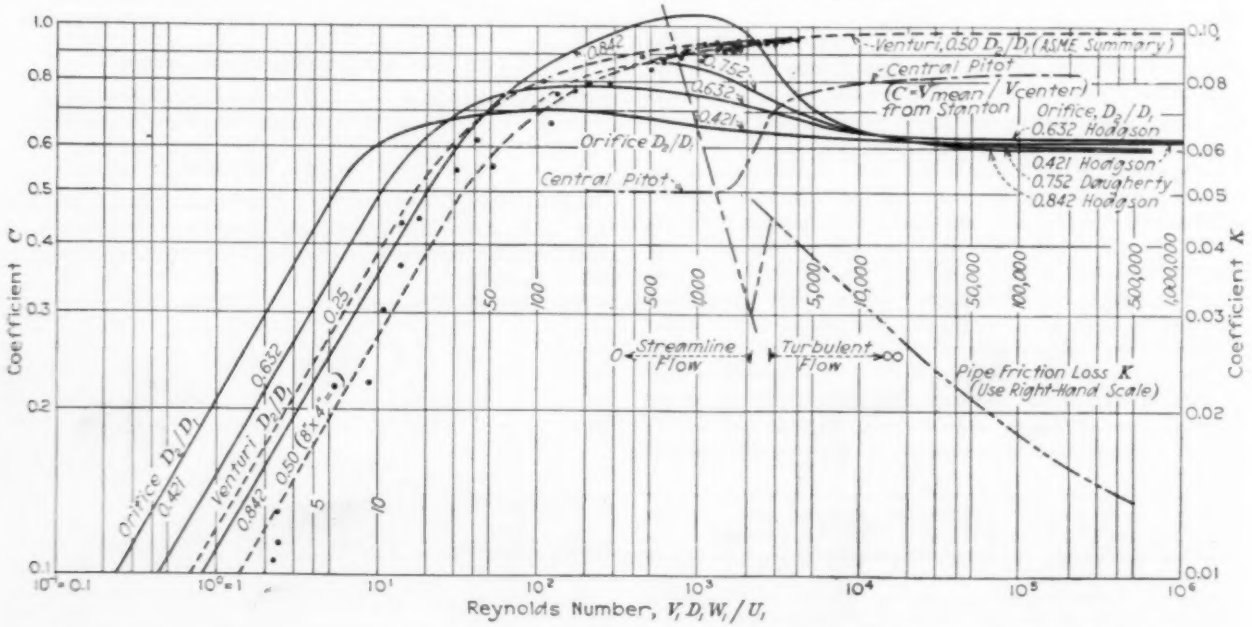

Fig. 1 Fluid-Meter Coefficient C and Pipe-Friction Loss K Plotted Against Reynolds' Number $V_1 D_1 W_1 / U_1$

that a nearly straight-line relation exists for all values of the expansion correction y and the acoustic ratio x/n. The expansion factor Y depends on the correction y as follows:

$$Y = 1 - y \quad [5]$$

It is generally most convenient to apply this nearly straight-line relation by using one of the following equations:

$$y = bx/n \quad [6]$$

$$Y = 1 - bx/n \quad [7]$$

since b is practically constant. (R-5, R-6.)

Fig. 4 shows the relation between b and the ratio of diameters d_2/d_1 for the venturi tube or nozzle, and also for square-edged orifices with flange taps.

Another familiar form involves taking the square root of a similar factor:

$$Y = \sqrt{1 - b'x/n} \quad [8]$$

However, the simpler form (which does not include the radical), $Y = 1 - bx/n$, as used above, is satisfactory for general commercial

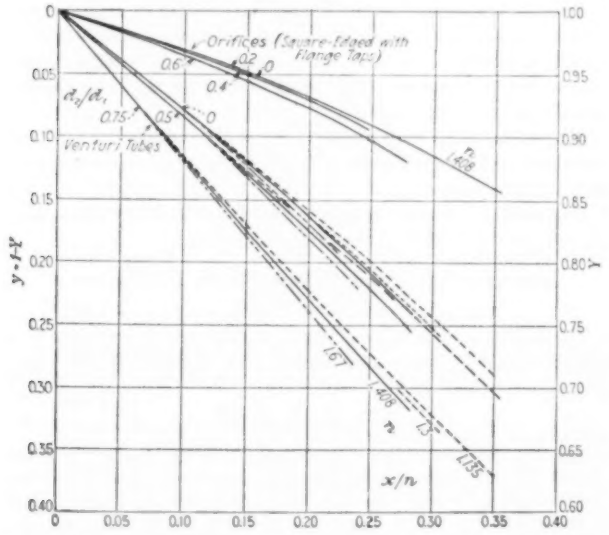

FIG. 2 RELATION BETWEEN EXPANSION FACTOR Y AND ACOUSTIC RATIO x/n

(Orifice data from U. S. Bureau of Stds. R.P.49.)

use, since the error produced by this approximation is generally less than 0.2 per cent; and also it will be observed that some adiabatic corrections for venturi tubes are concave upward and some the reverse.

In 1914, G. B. Upton used the following formula for venturi tubes: $b = (3 + R^4)/4(1 - R^4)$, where $R = d_2/d_1$.

For most orifices the use of the separate factors C and Y determined above will be entirely satisfactory. However, for very small orifices or highly viscous gaseous fluids it may be necessary to use the experimentally determined combined factor CY plotted against the Reynolds number for various acoustic ratios.

Although the use of the simple acoustic ratio x/n is only shown for nearly adiabatic expansions, this method will be found useful where the flow through the differential producer follows a somewhat different expansion law (as with orifices with pipe connections which really measure the "loss" due to the throttling orifice). This is due to the fact that the acoustic ratio x/n is primarily based upon the use of the velocity of the fluid in the pipe at the inlet and the acoustic velocity also at the same point, and at the usual low differentials the velocity of sound will not change appreciably along the differential producer.

The above method of metering uses only known quantities in the hydraulic formula, and the experimentally determined factors, coefficient C and expansion factor Y, are obtained from two dimensionless ratios (Reynolds' number and acoustic ratio), both of which depend only upon known quantities. Since both the Reynolds number and acoustic ratio are based upon the conditions in the pipe at the inlet of the differential producer, the above method is suitable for use with any geometrically similar differential producers.

STANDARD DIFFERENTIAL PRODUCERS—DEFINITIONS

Venturi Tube. The term "venturi tube" refers specifically to a constant-angle conical contracting inlet section having a

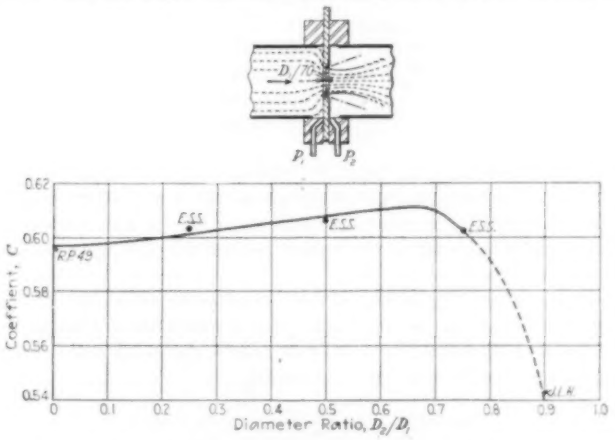

FIG. 3 RELATION BETWEEN "FLAT" COEFFICIENT C FOR SQUARE-EDGED ORIFICES WITH FLANGE TAPS AND DIAMETER RATIO D_2/D_1 AT HIGH VALUES OF REYNOLDS' NUMBER

cylindrical inlet and throat with gently curving transition surfaces, and having an annulus at both inlet and throat. A downstream pressure-recovery constant-angle cone is generally added to reduce the loss of head to a minimum, the overall length depending also upon the throat diameter.

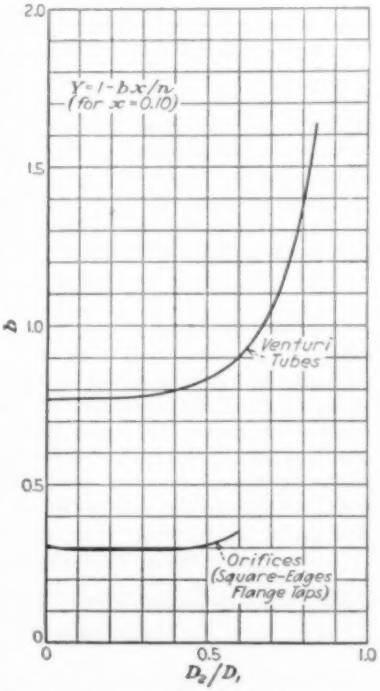

FIG. 4 RELATION BETWEEN EXPANSION CONSTANT b AND DIAMETER RATIO D_2/D_1 FOR VENTURI TUBES AND SQUARE-EDGED ORIFICES

Venturi Nozzle. The venturi nozzle consists specifically of a conoidal contracting section containing an inlet and throat connections each having an annulus (as with standard venturi-tube construction, hence "venturi" nozzle). Although there is generally no downstream recovery cone, a short cone is sometimes added which cuts the loss practically in half. This venturi nozzle is generally somewhat shorter between inlet and throat connections than the standard venturi, one pipe diameter being the standard distance between connections; the overall length is the same for a given pipe size regardless of the size of the throat.

Venturi Nozzle-Tube. This is merely the venturi nozzle with an added short recovery cone (of standard length regardless of diameter ratio).

Flow Nozzle. The flow nozzle consists merely of a nozzle-

shaped constriction which is placed between two pipe flanges. There is no annulus at either section, both connections being generally made in the wall of the pipe near the nozzle, as with square-edged orifices.

Square-Edged Orifice With Flange Connections. This consists generally of a concentric circular aperture in a thin-plate diaphragm, having single upstream and downstream pressure connections in the flanges immediately adjacent to the orifice, or in the face of the orifice itself. The leading edge of the orifice is square-edged, while the downstream edge may be beveled to make the thickness at the edge less than one-seventieth of the pipe diameter.

Square-Edged Orifice With Throat Connections. With an orifice between flanges as before, single connections are made to the pipe wall at 1 pipe diameter upstream and $^1/_2$ pipe diameter downstream, the latter corresponding roughly with the *vena contracta*.

Square-Edged Orifice With Pipe Connections. With an orifice between flanges as before, single-point connections are made in the wall of the pipe at $2^1/_2$ pipe diameters upstream and 8 pipe diameters downstream from the orifice.

II—BASIC FORMULA FOR QUANTITY-RATE METERS

General Principles

The common characteristic which classes the quantity-rate meters together is that the flow through the differential producer causes a pressure difference which the secondary element then uses as an indication of the rate of flow. This difference may be between the pressure at two different sections of the stream, as in the venturi tube, flow nozzle, and orifice meters, or it may be the difference between pressures at two points in the same section of a curved stream, as in the centrifugal meter and the flow bend, or, finally, it may be the difference between pressures at the same point, as in the pitot or impact-tube meter. To have calibrations apply generally, it is necessary to use geometrically similar differential producers.

Relation of Differential to Rate

Generally there is a simple relation between the quantity-rate and the differential: it is, as a rule, almost exactly proportional to the square root of the differential. The proper multiplier is usually determined by calibration against a basic standard, measuring the actual volume or weight in a certain period of time. The multiplier depends primarily on the shape of the differential producer, including the usually slight effect of the roughness, the size of the pipe and the density of the fluid.

Basic General Formula

The above relation can be expressed in the following equation:

$$Q_1 = kD_1^2 \sqrt{P/W_1} \quad \ldots\ldots [9]$$

which does not involve gravitation in any way.[6] The following notation is employed:

Symbol	Dimension	Unit	Quantity
Q_1	L^3/T	Cu. ft. per sec.	Quantity-rate of flow under upstream conditions
k	....	.....	Constant determined by calibration
D_1	L	Ft.	Diameter of pipe
W_1	M/L^3	Lb. per cu. ft.	Density of fluid under upstream conditions
P	M/LT^2	Poundals per sq. ft.	Differential pressure

However, Equation [9] may be rewritten as

$$Q_1 = kD_1^2 \sqrt{gH_1} \quad \ldots\ldots [10]$$

where

H_1	L	Ft.	Differential head of the fluid itself (of density w_1) acted upon by gravity
g	L/T^2	Ft. per sec. per sec.	Acceleration of gravity

The constant k, as determined by calibration, is found to depend upon the size and shape of the differential producer—including the usually slight effect of roughness in the differential producer and also of the pipe itself as well as the influence of fittings, upstream especially, and the amount of straight pipe between them and the differential producer; this constant k being expressed as a function of the Reynolds number, which relates the quantity-rate of flow, size of pipe, and the density and viscosity of the fluid.

Where the fluid is gaseous, there is the additional effect of the usually slight expansion of the fluid as it passes through the differential producer.

Differential producers generally used for closed conduits (pipes) are the venturi tube and the thin-plate orifice.

Derivation of Basic Formula From Dimensional Homogeneity

The basic formula for any shape of differential producer is as follows, being dimensionally correct, and does not depend upon gravitation in any way:

$$Q_1 = kD_1^2 \sqrt{P/W_1} \quad \ldots\ldots [9]$$

---

[6] In the basic formulas throughout this work, the unit "pounds" means "pounds mass" (the British "absolute" unit) instead of "pounds force" (the customary "engineering" or "gravitational" system, also known as the "foot-pound-second" system). This absolute system has been used in these notes to avoid the misleading appearance of the symbol g in a formula, e.g., Equation [9], expressing a physical relation into which gravitation absolutely does *not* enter.

Referring to the unfortunate customary use of "pounds force," when it falsely appears to involve gravitation in such equations, Lord Rayleigh wrote (R-7):

"Engineers, who might make much more use of it (the principle of similitude) than they have done, employ a notation which tends to obscure it. I refer to the manner in which gravity is treated. When the question under consideration depends essentially upon gravity, the symbol of gravity g makes no appearance; but when gravity does not enter into the question at all, g obtrudes itself conspicuously."

Since it is necessary to make use of viscosity in metering fluids, it is important that the relatively unfamiliar units for viscosity be clearly expressed in absolute units, their use for this quantity having been established by physicists in practically all available published data.

"It is not desirable to tabulate viscosities in gravitational or engineers' units, as such values involve the value of g, which varies from place to place (R-8)."

The British "absolute" system of units has been used in this work since it corresponds dimensionally throughout with the metric "absolute" or c.g.s. system of units. Although there should be no confusion concerning the units for length and time, it may be well to make the following statement concerning mass and force units, as related by the gravitational acceleration g:

In (metric) absolute c.g.s. units, a force of one dyne will give a mass of one gram an acceleration of one centimeter per second per second. Correspondingly in (British) absolute f.p.s. units, a force of one poundal will give a mass of one pound an acceleration of one foot per second per second.

The international gravitational standard at sea level and 45 deg. latitude is that it takes 32.174 poundals to make one pound of force, in the customary "engineering" units.

A fluid, water, may have a density (mass per unit of volume) of 62.37 lb. per cu. ft. at 60 deg. fahr. A cubic foot of this fluid would then weigh (exert a force of) 62.37 lb. in the customary engineering or gravitational units under the acceleration of gravity g. This weight-force would then equal $g \times 62.37$ or $32.174 \times 62.37 = 2{,}007$ poundals, i.e., expressed in absolute force units. This system gives the mass discharge in customary units, and since the differential pressure is ordinarily expressed as head, there is practically no use made of the unfamiliar "poundal."

where P and W_1 are expressed in mass units. However, $P/W_1 = gH_1$, as will be immediately recognized since $P = W_1gH_1$. Writing the formula for both the quantities and their dimensional units:

$$Q_1 = kD_1^2\sqrt{2gH_1} \quad \ldots\ldots\ldots\ldots\ldots [11]$$

and

$$\frac{\text{ft.}^3}{\text{sec.}} = \text{ft.}^2\left(\frac{\text{ft.}}{\text{sec.}^2} \times \text{ft.}\right)^{1/2} \quad \ldots\ldots\ldots\ldots [12]$$

$$= \frac{\text{ft.}^3}{\text{sec.}}$$

It is seen that the dimensions on both sides of the equation are equal.

The factor k may equal the coefficient C or may include some constant which will make the equation either more convenient to use, or cause the value of the coefficient C to have some particular physical significance, such as the correction for friction in the inlet cone of a venturi tube or the correction for the combined effects of contraction and friction in the square-edged orifice, having pressure connections one diameter upstream of the orifice and at the *vena contracta* downstream.

It should be observed here that the relation between differential pressure and quantity is perfectly general for any shape of differential producer which is exposed to the dynamic action of a flowing stream of fluid in a closed conduit. This formula may be used in connection with such diverse differential producers as friction loss in a length of straight pipe, square-edged orifice, venturi tube, pitot tube, elbow, or other fixed shape.

III—COEFFICIENT AND EXPANSION FACTOR CORRELATED BY DIMENSIONLESS RATIOS

Coefficient and Reynolds' Number

Physical Significance of Reynolds' Number. The various factors entering into the Reynolds number are qualitatively related as follows (R-4):

Consider a fluid without appreciable viscosity flowing in a closed conduit. This fluid would have only inertia forces called into play by its movement. These inertia forces are proportional to the density.

Density and Viscosity. In any real fluid there will necessarily be some effect of viscous forces. The degree to which they modify the motion of the liquid depends on their relative magnitude in comparison with the inertia forces. Hence with fluid flow the significant property of the fluid is not simply its viscosity U nor its density W, but the ratio of viscosity to density, or

$$U/W = \underline{KV} \quad \ldots\ldots\ldots\ldots\ldots [13]$$

which is known as its "kinematic" viscosity.

In flow through a nozzle or orifice the viscous forces increase in direct proportion to (V) the velocity of flow of the fluid. The kinetic energy, or inertia forces, increase with (V^2) the square of the velocity. Hence the effect of viscosity is relatively less at high than at low velocities; thus, increasing the rate of discharge has qualitatively the same effect on the discharge coefficient as decreasing the kinematic viscosity.

Diameter. Consider another nozzle or orifice, geometrically similar to the one just discussed, i.e., of the same shape but smaller. Reducing the size of the differential producer without reducing the velocity of flow through it increases the viscous shear, or the transverse gradient of velocity across the flow, and thus increases the viscous forces which are proportional to the shear.

The influence of viscosity is therefore greater on small than on large differential producers. Thus, reducing the diameter has qualitatively the same effect on the coefficient as increasing the kinematic viscosity of the fluid.

Combination as Reynolds' Number. Since the foregoing conclusions are relative to the effect of the kinematic viscosity, the coefficient for differential producers of any one shape can be expressed by some function of the ratio

$$R = VD/\underline{KV} = VDW/U \quad \ldots\ldots\ldots\ldots [14]$$

in which V is the mean axial velocity through the nozzle or orifice —computed from the known diameter D and the actual discharge-rate A, $\underline{KV}$ is the kinematic viscosity, U is the viscosity, W is the density of the fluid, and R is known as the Reynolds number.

The important conclusion is that the general relation holds for differential producers of any one shape, and that the coefficient C is a function of the Reynolds number, or

$$C = f(R) \quad \ldots\ldots\ldots\ldots\ldots [15]$$

The relation between fluid-meter coefficients and the Reynolds number has been shown in Fig. 1, which gives an airplane view of the general situation. Although the central pitot tube would seem to make an ideal oil meter in the streamline-flow régime still the maximum velocity is liable not to be in the center of the pipe, and such a meter would not be accurate. In the usual turbulent régime the venturi-tube coefficients are seen to be quite close together while there is considerably more variation for the orifices.

Derivation From Dimensional Homogeneity. For geometrically similar differential producers in closed conduits, through which fluids flow, having no appreciable effects of compressibility or change of density, the discharge coefficient for a fluid will depend in part upon the rate of discharge. The actually effective properties of the fluid are its density and viscosity.

The relation connecting the discharge coefficient C with the velocity of flow V, the density W, and the viscosity U of the fluid, and the diameter D of the differential producer may be expressed by the equation

$$C = f(V, D, W, U) \quad \ldots\ldots\ldots\ldots\ldots [16]$$

The value of the function f must be determined by actual experiment; however, it is certain that some relation exists between this function f and these variables, since all of the variables which have actually been found by experiment to affect the coefficient are included, and nothing else of importance enters in usual practical metering of fluids.

For a differential producer of another shape the function f would obviously be changed somewhat, but where the form is limited to one shape there can only be one relation of the function f to the other factors. Since the value of the function f, which takes complete account of the shape, must be determined by actual experiment, it makes the relation, which is entirely independent of the shape, perfectly general for any type of differential producer.

The essence of the law of dimensional homogeneity is that the dimensions on both sides of an equation must be equal as well as the numerical values of the various quantities.

The discharge coefficient C is dimensionless, for it is a pure ratio of the actual value of the rate of flow V as compared with the theoretical value determined from the fundamental relation without any coefficient.

Hence each combined term of the second member of the equation must be dimensionless, regardless of the unknown form of the function f itself. While none of the quantities V, D, W, or U themselves satisfy this requirement, still it was

early found by Reynolds that the combination R (the Reynolds number) does.

$$R = VDW/U \quad [14]$$

as can be seen by equating the units:

$$\frac{\frac{\text{ft.}}{\text{sec.}} \times \text{ft.} \times \frac{\text{lb.}}{\text{ft.}^3}}{\frac{\text{lb.}}{\text{sec.} \times \text{ft.}}} = 1 \quad [14a]$$

This is the only combination that does satisfy this requirement,[7] and consequently the coefficient must be a function of the Reynolds number only,[8]

or

$$C = F(VDW/U) = F(R) \quad [15]$$

The value of F must be found from experiment, but there is now only one independent variable R instead of four: V, D, W, and U.

Expansion Factor and Acoustic-Velocity Ratio

The correction for expansion must also be dimensionless as it is also a true ratio or coefficient, and consequently must depend upon terms which are themselves dimensionless. It is obvious that the ratio of the differential pressure to the inlet pressure, P/P_1, would be dimensionless, and the expansion correction should be some function of P/P_1. Where the acoustic velocity (velocity of sound) is significant, it will be seen that the ratio of the velocity of flow and the acoustic velocity, V/V_a, is also dimensionless, and consequently this acoustic-velocity ratio should be useful for this type of flow. The usual adiabatic-expansion correction is seen to be composed purely of dimensionless ratios—for the pressures and the specific heats, which correspond with the relations obtained if the velocities of flow and sound are expressed mathematically.

It should be realized, however, that there is a fundamental difference in the performance of fluid meters measuring liquid and those measuring gaseous fluids, in that liquids do not change density appreciably with the usual small differential pressures occurring in fluid meters, whereas gaseous fluids may, particularly where the initial pressure is low.

A further limitation for gaseous-fluid meters is that the absolute pressure at the greatest flow constriction should exceed approximately one-half of the inlet pressure, as otherwise the rate of flow will depend entirely upon the inlet pressure, being practically directly proportional to it, this being generally known as Napier's relation. At this critical pressure the velocity of the fluid at the point of maximum constriction becomes equal to the velocity of sound, and the acoustic-velocity ratio thus becomes unity. Under these conditions the usual differential pressure relation becomes useless for metering purposes.

Derivation of Expansion Factor "Y" From Dimensional Homogeneity. For use with any shape of differential producer, the known upstream conditions are used. The dimensionless expansion factor Y is seen below to be a function of the dimensionless ratio V_1/V_a, where V_1 is the mean velocity of the fluid at the inlet and V_a is the acoustic velocity (velocity of sound) under the inlet conditions.

The expansion factor Y is dimensionless and consequently must depend upon that dimensionless ratio which contains all of the pertinent variables which affect the expansion of the fluid. The velocity V_1 of the fluid and the acoustic velocity V_a together contain all of these pertinent variables. The ratio of the two velocities V_1 and V_a is necessarily dimensionless, being known as the acoustic-velocity ratio V_1/V_a, which forms the basis upon which the expansion factor Y must necessarily depend.

$$V_1 = \frac{Q_1}{A_1} = \frac{CY}{\sqrt{(D_1/D_2)^4 - 1}} \sqrt{2P/W_1} \quad [17]$$

and

$$V_a = \sqrt{\frac{nP_1}{W_1}} \quad [18]$$

so that for a "flat" coefficient C,

$$V_1/V_a = k_1 Y \sqrt{\frac{x}{n}} = \text{the acoustic-velocity ratio} \quad [19]$$

where

$$x = P/P_1 \quad [20]$$

is the ratio of differential to upstream pressure, n = the ratio of the specific heats, and k_1 a constant.

However, for each value of the "acoustic-velocity ratio" there is a corresponding value of x/n, namely, the "acoustic ratio" R_{a1}, or

$$Y = f_1(V_1/V_a) = f_2(Y^2 x/n) = f(x/n) \quad [21]$$

by dimensional homogeneity.

The acoustic ratio x/n for the inlet conditions will be used since it involves only known quantities and is directly proportional to the square of the acoustic-velocity ratio at ordinary low differentials.

If the acoustic-velocity ratio is taken at the "throat" conditions—Section 2—for a venturi tube (or the corresponding *vena contracta* conditions for an orifice), the corresponding factor (R-8) for the acoustic ratio R_{a2} under these conditions, assuming adiabatic expansion, is

$$\frac{(P_1/P_2)^{\frac{n-1}{n}} - 1}{(n-1)\left[1 - (D_2/D_1)^4 (P_2/P_1)^{2/n}\right]} = R_{a2} \quad [22]$$

The relation of the acoustic ratios[9] at the inlet and throat, R_{a2}/R_{a1}, is shown on Fig. 5. Although (for infinite D_1) $R_{a2} = 0.5$ when $V_2 = V_a$, regardless of the value of the specific-heat

[7] See Appendix No. 3 for conventional derivation, equating dimensional exponents.

[8] Where V, D, W, and U and the geometrical shape of the differential producer are the only pertinent variables.

[9] If the ratio R_{a1}/R_{a2} was a single-valued function in spite of variation of the specific-heat ratio n, exact correspondence could theoretically exist between the coefficient and R_{a2} at the throat, R_{a1} at the inlet, or R_a at any section between them. (J. L. Hodgson states that the coefficient does not depend exactly upon the acoustic-velocity ratio taken at either the throat or upstream, but instead at some point between them.)

The choice of "corresponding" functions, such as the acoustic ratio x/n for the acoustic-velocity ratio V_2/V_{a2}, requires careful judgment since the simple mathematical laws underlying "correspondences" are not adequately covered in conventional engineering courses, and since such a change of function is usually made, in fact, to avoid involved mathematical expressions which are difficult to visualize.

The basis for primary "correspondence" is (as its name implies) that for each point on one surface there will be a single corresponding point on another surface. This essential requirement was not met by Odquist, who attempted to substitute the simple pressure ratio P_2/P_1 (a function of pressure only) for the acoustic-velocity ratio V/V_a (a function of both the pressure ratio P_2/P_1 and the specific-heat ratio n). Odquist also substituted the acoustic velocity V_a for the fluid velocity in the Reynolds number, and thus obtained (R-9) a physically meaningless ratio $V_a DW/U$, which with P_2/P_1 becomes absurd when the fluid is a liquid.

It is desirable to use only basic dimensionless ratios which have clear physical meaning; the Reynolds number VDW/U (or its equivalent QW/DU) which defines the degree of "turbulence" in the fluid, and the acoustic-velocity ratio V/V_a (or its equivalent, and more convenient, acoustic ratio x/n). Both of the ratios ($V_1 D_1 W_1/U_1$ and x/n) finally chosen by the author retain their physical meaning for either liquid or gaseous fluids.

ratio, still it will be found that Y then varies considerably, as below:

$$Y = \sqrt{\frac{n}{n-1}\left(\frac{2}{n+1}\right)^{\frac{2}{n-1}} \frac{1-\frac{2}{n-1}}{1-\left(\frac{2}{n-1}\right)^{\frac{n}{n-1}}}} \quad \ldots [23]$$

$$\frac{P_2}{P_1} = \left(\frac{2}{n+1}\right)^{\frac{n}{n-1}} \text{ for } D_2/D_1 = 0 \ldots\ldots [24]$$

assuming adiabatic expansion as above.

In fact, the expansion factor Y varies less with changes of the specific heat ratio when R_{a1} is used, although R_{a1} does not have a constant value when the velocity of sound is reached at the throat.

With the velocity of sound at the throat, for $D_2/D_1 = 0$,

with	n =	1.135	1.408	1.67
	x =	0.422	0.473	0.513
	x/n =	0.372	0.336	0.307

Obviously the only basis which would give a constant value of the expansion correction at the acoustic velocity, regardless of

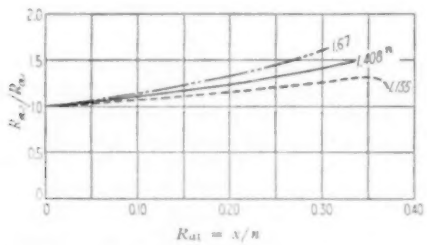

FIG. 5 RELATION OF ACOUSTIC RATIOS AT INLET AND THROAT CONDITIONS FOR VENTURI TUBES

changes of the specific-heat ratio, would be the complete adiabatic expression itself, and this would hardly be convenient or practicable to use for usual commercial metering. Besides, this expression is based on the assumption of purely adiabatic flow and so is not suitable for general use. The "throttling" orifice with distance pressure connections, which measures only the "loss," may possibly do violence to this assumption.

In view of the foregoing, the use of the known conditions upstream has been adopted in these notes for the acoustic-ratio basis for the expansion correction factor. Incidentally, it would be difficult in practice to measure the temperature at the throat.

REYNOLDS' NUMBERS, SIMILARITY, AND COEFFICIENTS

The following example illustrates the relation which exists between Reynolds' numbers, similarity of flow and structure, and coefficients. It may also assist in defining these terms as used in this work.

The flow Q through a closed conduit is divided into two streams, see Fig. 6, one of which flows through a long capillary tube M in which the resistance to flow is due to viscous forces, and the other stream through a nozzle N or orifice in which the resistance to flow is due to the inertia of the fluid.

The pressure differential P, due to viscous friction, across the ends of the tube is proportional to the viscosity and to the rate of flow Q_m through the tube. This same pressure differential P, due to inertia forces, across the ends of the passage containing the nozzle is proportional to the density and to the square of the rate of flow Q_n through the nozzle.

Relation of Similarity to Reynolds' Numbers. Similarity of flow requires that the streamlines, which necessarily follow the flow distribution, be similar in shape and that the velocities or ratios of flows be in the same proportion at all places in the conduit. The ratio of the two branch flows, Q_m/Q_n, through the capillary tube and the nozzle may be found from the relation that the same differential pressure exists across the ends of both branches.

For a capillary tube J diameters long, the differential pressure P depends upon the flow Q_m, the viscosity U, and the capillary-tube diameter D_m as follows:

$$P_m = J\,k\,U\,V_m/D_m \ldots\ldots [25]$$

and since $Q_m = k_1\,V_m D_m^2$,

$$P_m = K_m\,U\,Q_m/D_m^3 \ldots\ldots [26]$$

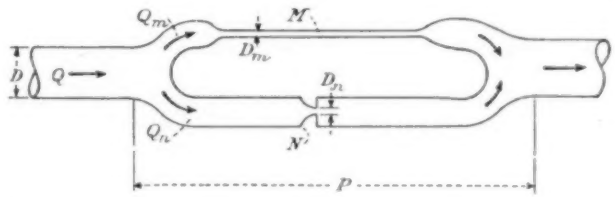

FIG. 6 DIVIDED CONDUIT WITH VISCOUS AND INERTIA FORCES ACTING IN PARALLEL

For the nozzle, the differential pressure depends upon the flow Q_n, the density W, and the nozzle diameter D_n as follows:

$$P_n = K\,W\,V_n^2 \ldots\ldots [27]$$

and since $Q_n = K_2\,V_n D_n^2$,

$$P_n = K_n W\,Q_n^2/D_n^4 \ldots\ldots [28]$$

Since these two differential pressures are equal, or $P_m = P_n = P$, the ratio S of flows Q_m/Q is defined as follows:

$$Q = Q_m + Q_n \ldots\ldots [29]$$

Letting $D_m = mD$ and $D_n = nD$, $Q_m = SQ$ and $Q_n = (1-S)Q$.

$$P_m = K_m\,U\,S\,Q\,/m^3D^3 \ldots\ldots [30]$$

and

$$P_n = K_n W\,(1-S)^2\,Q^2/n^4D^4 \ldots\ldots [31]$$

Then equating P_m and P_n,

$$\frac{(1-S)^2}{S} = \frac{K_m n^4\,UD^4Q}{K_n m^3\,WD^3Q^2} = \frac{K_m n^4\,UD}{K_n m^3\,WQ} \ldots\ldots [32]$$

and since $Q = k_2\,V\,D^2$,

$$\frac{(1-S)^2}{S} = b\,\frac{U}{WVD} = b/R \ldots\ldots [33]$$

where $R = VDW/U$ or the Reynolds number.

$$S^2 - (-2 - b/R)\,S + 1 = 0 \ldots\ldots [34]$$

$$S = \frac{(2 + b/R) - \sqrt{(2 + b/R)^2 - 4}}{2} \ldots\ldots [35]$$

following the usual quadratic solution. However, the value of S must be from zero to unity and so the positive value of the radical is omitted as having no physical meaning.

$$S = f_1(R) \quad \text{and} \quad (1-S) = f_2(R) \ldots\ldots [36]$$

Thus the ratio of flows, i.e., "flow similarity," is seen to depend only on the Reynolds number. Consequently for closed conduits, gravity has no effect upon the flow distribution; another proof of this is that it is well established that the direction of the axis of the flow in a nozzle with respect to the vertical has no effect upon the performance of the nozzle.

The direction of the flow lines themselves at the ends of the branch passages is also seen to be entirely dependent upon the Reynolds number.

Relation of Coefficient to Reynolds' Numbers. The differential pressure across the nozzle may be used to determine the rate of flow.

$$P = K_n W Q_n^2/D^4 = K_n W (1 - S)^2 Q^2/n^4 D^4 \ldots\ldots [37]$$

$$P = K_n W Q^2 f_2 (R)/n^4 D^4 \ldots\ldots\ldots\ldots [38]$$

and taking the square root of both sides,

$$Q = KD^2 \sqrt{P/W} \ldots\ldots\ldots\ldots [39]$$

where

$$K = f (R) \ldots\ldots\ldots\ldots [40]$$

or the coefficient depends upon the Reynolds number.

This is recognized as the fundamental equation for fluid meters in which the differential is created by the rate of flow. This formula holds rigorously for purely turbulent (non-viscous) flow, for mixed viscous and turbulent flow, and also for purely viscous flow—in other words, the formula is perfectly general.

While the mathematical treatment of the above derivation is based upon having purely viscous flow in the capillary tube and purely turbulent flow in the nozzle (or orifice), still it will be observed that the nozzle and the capillary tube are in parallel, and in case the flow in the capillary tube should have a slight inertia effect, or the flow through the nozzle should have a slight viscous effect, there would not be any change in the form of the equations as both types of flow are already in parallel and only the constants would be slightly affected. It may be noted that in ordinary turbulent flow in a closed conduit with ordinary smooth pipes, the turbulence is not complete but increases with the Reynolds number, the quantity of flow at the walls of the pipe in viscous motion decreasing and the quantity of flow in the center of the pipe in turbulent motion increasing correspondingly, both being in parallel.

The same fundamental equations involving terms of inertia—proportional to the density and the square of velocity, and terms of viscous resistance—proportional to the viscosity and the first power of the velocity, have been used heretofore to derive the relation between the type of flow and the Reynolds number. Although the equations and their results were undoubtedly correct, the physical significance of the various factors has not been entirely convincing. The present derivation from purely physical considerations constitutes a complete confirmation of the fact that both the similarity of flow and the coefficients depend only upon the Reynolds number, which number was derived originally from the simple law of dimensional homogeneity, i.e., the units on both sides of an equation must be the same. This latter purely mathematical derivation has also failed to satisfy completely the need for attaching a physical meaning to the Reynolds number. Consequently the present physical derivation may be of interest as presenting fairly and completely the relationship actually known from experiment to exist between Reynolds' numbers, similarity, and coefficients.

Notes on Fundamental Considerations for Flow Similarity

The rate of quantity discharge can depend only upon the shape and size of the differential producer, the various significant properties of the fluid, and the initial physical conditions, such as initial pressure and temperature besides the differential.

At the upstream connection the pertinent conditions may be exactly known.

At the downstream connection, with an actual fluid and shape where there is friction loss—involving viscosity, or a contraction—the amount of which depends upon the shape and also upon all of the factors affecting similarity of flow, the conditions of the fluid at the downstream connection will not in general be exactly determinable, and consequently may not be used as a rigorous basis for the fundamental relation between the quantity-rate of flow and the other pertinent variables.

Similarity of Flow. For identical coefficients, there must be exact geometrical similarity of shape of the differential producer and exact similarity of flow in the differential producer.

With a viscous liquid, the flow similarity will be determined by the shape and the Reynolds number. However, this relation itself may not be the only significant factor since temperature effects between the upstream and downstream connections are introduced by friction, which will have an effect upon the velocity distribution at the downstream connection. Also, in any actual differential producer there will be some transfer of temperature along the walls of the differential producer. The temperature-distribution effects are generally negligible for usual metering differential producers, although they may become appreciable in dealing with friction loss in pipe lines and with centrifugal pumps. The additional properties of the liquid which might be expected to become significant are the specific heat and conductivity and their relation to the temperature (as well as the temperature distribution and the temperature of the liquid), also the conductivity of the walls and the temperature distribution along these walls.

With a gaseous fluid, which is expansible and also viscous, the flow distribution simultaneously depends upon the Reynolds number and the ratio of the velocity of the fluid to its acoustic velocity. There will also be secondary effects of the temperature upon the significant properties of the fluid which may again be expected to depend upon the specific heats, conductivity, density, viscosity, and their relation to the temperatures and pressures of the fluid. There also will be some effect, as with a liquid, of the temperature distribution along the walls of the differential producer.

The acoustic velocity depends primarily upon the density, ratio of specific heats, and absolute pressure of the fluid, and it may vary somewhat from the upstream to the downstream connection. However, it may be exactly determined at the upstream connection, while at the downstream connection it may be somewhat uncertain due to the effect of the shape of the differential producer and the various secondary factors listed above. At this downstream connection, for example, there is likely to be an abnormal distribution of temperature, and hence density, and consequently also of the acoustic velocity, across the section.

Exact flow similarity will be approached most closely when a minimum effect is produced by other dimensionless ratios (besides Reynolds' numbers and acoustic-velocity ratios) which may involve secondary properties of the fluids and also temperature considerations. For the closest approach to the Reynolds number and acoustic-velocity ratio it seems preferable to use the exactly determinable conditions at the upstream connection, in view of the foregoing discussion.

Practical Metering Calculations. Coefficients are used in order to obtain a clear—usually a magnified—picture of some phenomenon. As many factors as possible, which have their relations definitely known, make up the body of the formula, while the remaining theoretically indeterminate values make up the coefficient. The conventional coefficient C for the venturi tube, for instance, expresses chiefly the excess pressure due to frictional resistance when the departure of the coefficient from its theoretically approximate limit of unity is considered, as above stated. For the liquid equation for square-edged orifices, the conventional contraction coefficient C indicates approximately

the value of the ratio of the area of the *vena contracta* to the orifice area. The usual point of interest, however, is to note the amount of departure from the usual value of approximately 0.6 due to various factors.

It is thus seen that the most physically significant dimensional value for a venturi tube is the throat area, or for a square-edged orifice is the corresponding area of the *vena contracta*. Further, in exceptional cases the inlet diameter may be so large that the velocity of approach has no significance. In this case the coefficient obviously depends upon the Reynolds number, using the throat diameter instead of the inlet diameter.

The Reynolds number chiefly determines the flow similarity, especially the coefficient expressing the amount of contraction at the *vena contracta* for the orifice, although for gases the latter will be increased slightly by the effect of expansion of the fluid at that section, with the acoustic-velocity ratio. This expansion-increased *vena contracta* is the proper constriction for use in the criterion for determining where the upstream pressure alone controls the rate of flow, i.e., where Napier's law comes into action. This point is the most important factor in controlling the type of flow, and consequently in actual use of the ratio of the velocity of the fluid to the acoustic velocity, the clearest physical picture is obtained from the use of the velocity of the fluid where the section of maximum constriction occurs. This section is at the *vena contracta*.

For very high speeds exceeding that of sound, it has been shown that stationary pressure waves occur (R-10).

IV—OTHER FACTORS AFFECTING THE COEFFICIENT

The foregoing proofs of the applicability of the Reynolds number for determining coefficients for geometrically similar differential producers in closed channels show conclusively that the method is rigorously correct when the flow depends exclusively, as it actually does in general, upon the factors included in the number itself. It must be understood, however, that there are certain definitely predictable conditions which introduce additional factors. One familiar case which already has been discussed is the correction for compressibility of gaseous fluids. There are a number of other conditions which may affect the flow distribution and consequently the coefficient. The existence of these other conditions in no way undermines the correctness of this method of "flow similarity" as the use of Reynolds' numbers is coming to be generally known, but merely requires that the additional physical conditions be taken into consideration, either by correcting for them or by eliminating the troublesome conditions.

Although some of these conditions have been discussed above, it is well to group them together here so that the limitations may be more readily recognized as they occur and to lend confidence to the use of coefficients determined from Reynolds' numbers without correction when these disturbing conditions do not occur. The method of similarity, i.e., Reynolds' numbers, is the only rigorously correct general method for correlating coefficients for fluid meters, and it may be used with entire confidence.

The flow distribution and coefficient depend basically upon the Reynolds number. Even when the coefficient is "flat"—i.e., such changes of diameter of pipe, the velocity, density, and viscosity of the fluid as occur in ordinary fluid measurement, with a particular meter, have no appreciable effect—still the coefficient actually depends on the Reynolds number, and its value sets the limits over which the coefficient may be safely used as being "flat."

Summary of Other Factors Affecting the Coefficient

Other factors affecting the coefficient are the following:

1 Gravity, only in "open channels"
2 Plastic fluids, not having true viscosity
3 Shape, size, and roughness, defined for true geometrical similarity
4 Discontinuity of flow, absolute pressure too low
5 Non-homogeneous fluids
6 Gaseous fluids, effects of expansion, and Napier's law
7 Dirty fluids, effects in practice
8 Non-uniform rate of flow.

Gravity. The differential producer and the conduit in which it is located must be closed—not have any surface exposed to the flowing stream which is not guided by fixed solid walls; i.e., there must not be any "free" surface or boundary between liquid and gaseous fluid. Where a "free" surface, due to gravity, occurs, there may be wave effects produced which modify the flow distribution and affect the coefficient. In this case an additional factor is seen to affect the coefficient, this factor being the ratio of the wave height to the square of the fluid velocity divided by twice the acceleration of gravity.

For similarity of flow through geometrically similar open channels, there necessarily will be a simple proportion between the wave height and any dimension of the channel such as its depth (R-11), and consequently this known fixed linear dimension may be used instead of a variable fluid dimension. This additional term (Froude's ratio) for similarity may thus be written:

$$2gL'/V^2 \qquad [41]$$

where the following notation is used:

Symbol	Dimension	Unit	Quantity
g	L/T^2	Ft. per sec.^{2}	Acceleration of gravity
L'	L	Ft.	Depth or other dimension of the channel
V	L/T	Ft. per sec.	Velocity of flow in the channel

A simple additional test to apply to determine whether gravity affects the coefficient is to consider whether a change of position of the differential producer relative to the vertical will cause a difference in the flow-distribution. Gravity not only has magnitude but also has direction, being a true vector quantity; consequently, if it has any effect, this effect must be influenced by direction. It is established universally that the position of differential producers in closed conduits with reference to the vertical has no effect whatsoever upon the coefficient and consequently "gravity" cannot enter as an additional limitation to the Reynolds number so long as the fluid fills the conduit and is of substantially homogeneous density throughout.

Plastic Fluids. There are some liquids which are only semi-fluids, being known as plastic or non-Newtonian fluids. Plastic solids do not flow until a finite force acts, but although plastic liquids flow slowly under infinitely small forces, still the rate of shear is not exactly proportional to the pressure. The absolute viscosity as used in the Reynolds number is not strictly applicable, and consequently the measurement of a plastic liquid with a differential type of meter involves additional difficulties. A familiar example of a plastic solid is a "grease" which may be formed from a truly fluid oil by adding a sufficient quantity of soap, while a plastic liquid would be formed by adding a much smaller amount of soap to the oil so it still flows slowly with any finite differential but does not have a constant "viscosity."

Size, Shape, and Roughness. For strict geometrical similarity, the linear dimensions of the roughnesses of the surface must be proportional to the linear dimensions of the differential producers. For the commercial differential producer of usual size, such as a well-shaped venturi tube or nozzle or a sharp-edged

orifice with flange connections, the effect of having the same absolute roughness, instead of roughness proportional to the diameter, will only produce a slight effect upon the coefficient. For a venturi tube or venturi nozzle, the coefficient for a small diameter will be only slightly less than for a large-diameter meter since the additional roughness increases the differential slightly; while for a smaller sharp-edged orifice with flange connections the coefficient will rise only slightly since the additional roughness will slightly decrease the inward flow of the fluid which causes the *vena contracta*.

Strict similarity of shape of the differential producer also requires that the shape, including roughness, of the conduit which contains the differential producer must be similar and must have a proportional length of straight pipe upstream and downstream from the differential producer to insure that the coefficients obtained by calibration will apply to the meter in location for actual metering. The same number of diameters of straight pipe preceding the meter is more important generally than the length of straight pipe downstream of the meter, since the velocity distribution at the inlet ordinarily affects the differential pressure considerably.

Where the upstream shape is such that the fluid rotates in the pipe as it approaches a venturi tube, producing helical flow, the coefficient is experimentally found to decrease by an amount which depends upon the "pitch" of the helix and the amount of constriction of the tube. The loss across the ends of the tube correspondingly increases when the pitch of the helix decreases. The coefficient for swirling flow is nearly constant, being practically independent of the rate of flow.

For an orifice, the coefficient rises for small angles of twist and decreases for angles larger than approximately 45 deg.[9a]

Straightening vanes may be used to eliminate errors due to swirling flow.

The design of pressure holes also should be similar for various sizes.

Slight constrictions in penstock lines are frequently calibrated and used as differential producers. The change of velocity from the inlet to the throat is generally quite small and the friction effect of the walls of the penstock is relatively large so that the coefficient is likely to fall at low rates of flow much more than with a standard-design venturi tube. This constriction is usually located just above the scroll case containing the turbine gates, which are opened more or less as required by operating needs, and thus there is a veritable change of the shape of the differential producer; the velocity distribution across the constriction and hence the coefficient being related definitely to the gate opening. However, the total variation of head is usually small, and consequently the calibration will apply closely under the usual conditions of operation. Two methods of rating these penstock meters in commercial use are the "salt-velocity method" of Prof. C. M. Allen, and the "pressure-velocity method" of N. R. Gibson.

Discontinuity and Absolute Pressure. The fluid may fail to fill the conduit and discontinuous flow may develop when the centrifugal forces of the fluid streams exceed the force of the absolute pressure which tends to hold the fluid stream in contact with the solid guiding walls of the conduit or differential producer. Liquids are generally more sensitive to this limitation than gaseous fluids, because in a liquid there may be formed bubbles of gas, which had been absorbed and held in solution by the liquid under a higher pressure but which can separate out with a decrease in pressure. Also liquids which are near their boiling points, such as hot water from a condenser, cracked petroleum distillate, or liquid anhydrous ammonia which has not been supercooled, may flash into vapor and errors of considerable magnitude be produced. It should be observed, however, that only about one-half of the error due to change of density, for a given lowering of pressure, will occur with a differential-pressure meter as with a displacement-type meter, since for the differential meter the error in the rate varies as the square root of the density, and for the displacement meter varies directly as the density.

Where there is no dissolved gas in the liquid, the boiling point of the liquid determines the safe minimum pressure—obviously the liquid will vaporize if the vapor pressure is more than the pressure in the differential producer.

When a liquid leaves a condenser without being supercooled, i.e., being at its boiling point, and is stored at the same pressure in a receiver, a slight drop in pressure will cause some of the liquid to flash into vapor. In order to keep all of the fluid in the liquid state, it is necessary to supercool the liquid somewhat, using additional cooling surface, or to put it under higher pressure than exists at the surface in the receiver; in other words, to keep the outflow pipe, at all points, and differential producer below the hydraulic gradient, based on the liquid level in the receiver.

This rule also holds good for liquids containing dissolved gases, it being important not to have the absolute pressure drop below that at which equilibrium has been attained.

There is somewhat less tendency for the coefficient to be affected in the case of a venturi tube or nozzle having properly streamlined, solid guiding walls forming the constriction in which there is a minimum tendency for a free contraction to form at the throat, than for the square-edged orifice in which the constriction is formed by the inertia of the fluid where there is the likelihood of pockets of gas or "broomy" discharge occurring on the downstream side of the orifice. Also, with an orifice there is more probability of erroneous coefficients being caused by deposits of material, heavier or lighter than the fluid, in front of the orifice.

Further, where wet steam is being metered there is a greater tendency for the entrained liquid to be thrown out of the steam and to accumulate in front of the orifice, it being generally necessary to provide a small drain hole at the bottom of an orifice when installed in a horizontal main.

Where a "free" surface exists as with the flow over weirs, there are also the effects of still other factors besides those included in the Reynolds number such as surface tension, adhesion, the viscosity drag of the gas (usually air) around the falling stream, the effects of the gas entrainment, and finally the effect of "back water," which may cause the weir to be "submerged," also the nappe of the weir can cling or be free depending upon certain shape factors, involving the admission of air beneath the nappe, which may not be included in the design of the portion of the weir which is actually in the flowing stream.

Non-Homogeneous Fluids. Where wet steam is being accelerated in passing through a differential producer there is what is known as the "braking" effect of the drops of water in the body of the steam. The steam tends to speed up when it reaches the constriction, but the drops of water tend to continue in motion at the much lower velocity of the steam in the main pipe at the inlet. A similar braking action would be expected in measuring air conveying powdered coal or sawdust, even if the mean density could be satisfactorily obtained. An additional effect of "gravity" on the flow distribution occurs when the density of the fluid is not constant over a cross-section of the differential producer or conduit. For example, in a pipe line conveying hot oil under streamline-flow conditions, the central body of the stream will be hotter than the oil near the walls of the pipe and consequently will be lighter. This will cause it to rise or "nose up" from the center of the pipe and seriously affect

[9a] Personal communication from Prof. W. S. Pardoe, University of Pennsylvania Hydraulic Laboratory.

any differential meter. Also where flowing oil is being either heated or cooled while the flow is streamline, there will be abnormal velocity distribution since the velocity distribution across a section is highly sensitive to any change in the viscosity of the oil. These changes are quite severe for small changes of temperature with heavy petroleum oils. Furthermore, the effect of upstream fittings is more persistent when abnormal flow exists in the streamline régime, since a highly irregular stream of very hot oil sometimes will flow for many pipe diameters through a "bed" or channel of much colder, sticky, semi-solid oil.

Gaseous Fluids. For orifices, especially, there are sometimes considerable changes in the flow distribution with the changes of pressure that necessarily occur. There are also corresponding changes of fluid density which tend to enlarge the *vena contracta* and thus increase the coefficient. This effect must be determined experimentally, and is in addition to the effect which occurs in nozzles which can be computed from thermodynamic considerations. It is also entirely distinct from compressional-wave phenomena which only occur at high expansion ratios where the velocity approaches that of sound.

When the velocity through the constriction of the pressure-differential producer approaches the velocity of sound, the pressure downstream cannot "back up" against the rapidly moving stream and so the capacity of the differential producer depends only upon the upstream pressure, naturally rendering useless the usual formula, for the capacity, which depends normally upon the differential pressure. This critical point is usually where the pressure, at the point of maximum constriction, is about half the absolute inlet pressure. Interesting compressional waves occur downstream from these conditions. A familiar hydraulic analogy is the performance of the usual weir which has the discharge dependent upon the differential when the backwater is high enough so that the weir is "drowned," while the discharge depends only upon upstream head (pressure) when the backwater is low enough so that it cannot work back against the freely falling stream—this latter condition of flow being termed "shooting flow."

Fundamentally, gases act differently from liquids in that they change density appreciably with small pressure differences such as ordinarily occur in metering differential producers.

Dirty Fluids. For a limited number of fluids, such as blast-furnace gas, which are extremely liable to have deposits separate out, the sharp-edged orifice may be more easily cleaned and will not tend to be affected as much as the shaped nozzle. This is chiefly due to the fact that the maximum pressure drop does not occur at the plane of the orifice but at the *vena contracta*, and consequently the formation of deposits due to this cause at the orifice is minimized. Further, the venturi tube, which is the usual form of nozzle used for this service, has considerably less loss of head than the orifice producing the same differential, and it is the accepted practice to use a higher differential with the venturi tube and thus obtain the utmost range of measurement. This higher differential, while generally advantageous, increases the tendency for deposits to occur. Commercial designs of venturi tubes have been developed which facilitate cleaning the throat. Also, steam-jacketed venturi tubes are generally used for certain gases where naphthalene deposits would otherwise form; on the other hand, the sharp-edged orifice does not lend itself readily to this remedy. For large-ratio orifices, a very slight deposit affects the accuracy considerably.

Non-Uniform Rate of Flow. The coefficient depends upon an additional factor when the flow is not at a steady rate. Where the flow is pulsating in character, there may be vortex rings formed with sharp-edged orifices and some disturbance of the flow distribution, even with nozzles. This effect is independent of the effect of the average of the differentials being different from the average of the rates, and also of the errors caused by pressure waves occurring in the pressure pipes connecting the differential producer with the register. Furthermore, where the main pipe diameter is small, there will be impingement of the streams from the pressure pipes into the main stream which will seriously disturb the flow distribution, particularly in the streamline régime where the normally streamline flow may become turbulent in consequence of the disturbance at the pressure connections.

V—VENTURI-TUBE ANALYSIS

(This chapter, and the following, are merely illustrative material, offered as being of general interest)

Analysis for Liquids, Using Bernoulli's Theory. For liquids, a simple relation holds between the head H and the velocity V:

$$H = V^2/2g \quad \ldots\ldots [42]$$

$$V = \sqrt{2gH} \quad \ldots\ldots [43]$$

as is familiar to all hydraulic engineers.

Where fluid flows through a frictionless nozzle with no approach velocity, i.e., through an infinitely large inlet,

$$Q = AV \quad \ldots\ldots [44]$$

$$Q = A\sqrt{2gH} \quad \ldots\ldots [45]$$

where all the velocities V over area A must be equal and parallel. With an actual venturi tube in a pipe there will be some approach velocity, some friction from the inlet to throat, and the velocity distribution will not be uniform.

$Q = A_1V_1 = A_2V_2$ where the fluid is not compressible and there are no leaks between the inlet and throat, consequently

$$H = \alpha_2 V_2^2/2g - \alpha_1 V_1^2/2g + bV_1^2/2g$$

where α_1, α_2, and b are functions of the Reynolds number; α_1 and α_2 are factors for non-uniformity of velocity distribution and b depends upon the friction loss and change of turbulence between the inlet and throat.

For large D_2/D_1 ratio meters, α_1, α_2, and b may become relatively large, but for the usual ratios of standard commercial venturi tubes they are quite small. ($R = D_1/D_2$.)

$$\left.\begin{aligned} H &= \frac{\alpha_2 (D_1/D_2)^4 V_1^2 - \alpha_1 V_1^2 + bV_1^2}{2g} \\ &= \frac{(\alpha_2 R^4 - \alpha_1 + b)V_1^2}{2g} \end{aligned}\right\} \quad \ldots\ldots [46]$$

The theoretical head H_t is

$$H_t = (R^4 - 1)V_1^2/2g \quad \ldots\ldots [47]$$

whence

$$Q_1 = A_1V_1 = A_1\sqrt{2gH_t} = CA_1\sqrt{\frac{2gH_1}{R^4 - 1}} \quad \ldots\ldots [48]$$

Also

$$Q_1 = A_1\sqrt{\frac{2gH_1}{\alpha_2 R^4 - \alpha_1 + b}} = CA_1\sqrt{\frac{2gH_1}{R^4 - 1}} \quad \ldots\ldots [49]$$

and

$$C = \sqrt{\frac{R^4 - 1}{\alpha_2 R^4 - \alpha_1 + b}} \quad \ldots\ldots [50][95]$$

[95] Correspondence with Elliot E. Moody (Jun. A.S.M.E., Standard Oil Co., Bayway, N. J.) checks this method.

Referring to the basic formula [10], $Q_1 = kA_1\sqrt{gH_1}$, and the basic venturi formula

$$Q_1 = C\frac{A_1}{\sqrt{R^4-1}}\sqrt{2gH_1} \quad \ldots\ldots [51]$$

it will be found that the coefficient C or its components (α_1, α_2, and b) must be determined from actual experiment. The coefficient C depends on the shape and the Reynolds number, and the ratio $1/\sqrt{R^4-1}$ merely serves to make the coefficient more nearly dependent upon the variations from the ideal case. Consequently it is generally found to be most satisfactory to plot the coefficient C against the Reynolds number instead of attempting to make the above further analysis involving α_1, α_2, and b.

Analysis for Gaseous Fluids, Using St. Venant's Equation. If the fluid be a gas, its velocity at the throat of the venturi tube, due to its expansion, will be somewhat higher than it would be for a liquid. When the pressure drop is large in relation to the inlet pressure, the correction for expansion may be considerable. Assuming adiabatic expansion, i.e., frictionless flow, the gain in kinetic energy equals the potential energy liberated (per pound of fluid), or where $r = A_1/A_2$ and n = specific-heat ratio,

$$V_2^2/2 - V_1^2/2 = \frac{P_1}{W_1}\frac{n}{n-1}\left[1-(P_2/P_1)^{\frac{n-1}{n}}\right] \quad \ldots [52]$$

and for adiabatic expansion

$$W_2/W_1 = (P_2/P_1)^{1/n}, \quad \ldots\ldots [53]$$

and

$$Q_w = A_1V_1W_1 = A_2V_2W_2 \quad \ldots\ldots [54]$$

therefore

$$V_1 = V_2A_2W_2/A_1W_1 = V_2\,(1/r)(P_2/P_1)^{1/n} \quad \ldots\ldots [55]$$

and therefore

$$V_2^2\left[1-\frac{1}{r^2}(P_2/P_1)^{2/n}\right] = 2\,\frac{P_1}{W_1}\frac{n}{n-1}\left[1-(P_2/P_1)^{\frac{n-1}{n}}\right] \quad \ldots\ldots [56]$$

$$Q_w = A_2V_2W_2 = A_2V_2W_1\,(P_2/P_1)^{1/n} \quad \ldots\ldots [57]$$

$$Q_w = CA_2\left[\frac{2P_1W_1\,\frac{n}{n-1}\left(1-(P_2/P_1)^{\frac{n-1}{n}}\right)(P_2/P_1)^{2/n}}{1-\frac{1}{r^2}(P_2/P_1)^{2/n}}\right]^{1/2} \quad \ldots\ldots [58]$$

which is the general discharge formula required, where C is the discharge coefficient as determined by experiment.[10]

[10] It is obvious that if the coefficient C for a venturi tube is sufficiently low, the expansion will not be strictly adiabatic and some correction to the above formula will be necessary to take care of the different law of expansion.

For an orifice, the coefficient C must include both the friction coefficient C_r and the contraction coefficient C_c, also the proper value of the ratio of areas r to be used in this formula must be the ratio of the area of the pipe A_1 to the area at the *vena contracta* A_c, and

$$A_c = C_cA_2 \quad \ldots\ldots [59]$$

This method of treatment theoretically follows the actual physical phenomena most closely. However, it is customary to use the formula derived above, using the known orifice area A_2 in the ratio r. For more detailed discussion, see the section on orifice theory given later.

The coefficient C may include the effects of viscosity.

The actual volume Q_1 passing, measured at the upstream conditions P_1 and T_1 (and W_1), may be obtained from the relation

$$Q_1 = Q_w/W_1 \quad \ldots\ldots [60]$$

Since the full equation is inconvenient in actual use, it may be simplified (R-8) by combining it with the simpler formula obtained above, on the assumption that the fluid is incompressible, i.e., that W is constant.

To derive this formula, the loss of potential energy is equated to the gain of kinetic energy per pound of fluid between A_1 and A_2, thus:

$$\frac{P_1-P_2}{W_1} = \frac{V_2^2-V_1^2}{2} = \frac{V_2^2-\left(\frac{V_2}{r}\right)^2}{2} = \frac{V_2^2}{2}\left(1-\frac{1}{r^2}\right) \quad \ldots [61]$$

Therefore

$$V_2 = \left[(P_1-P_2)\,\frac{2r^2}{W_1(r^2-1)}\right]^{1/2} \quad \ldots\ldots [62]$$

Combining equations

$$Q_w = CA_2\left[(P_1-P_2)\,2W_1\,\frac{r^2}{r^2-1}\right]^{1/2} \quad \ldots\ldots [63]$$

This is the approximate equation corresponding to the adiabatic equation.

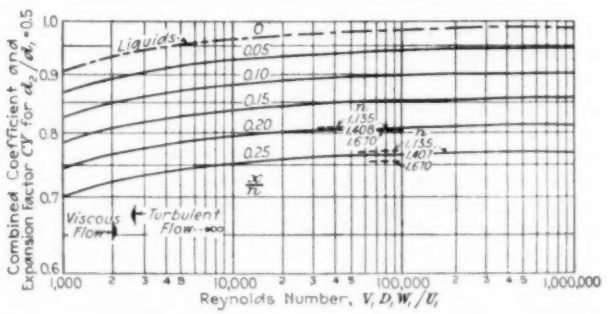

FIG. 7 RELATION BETWEEN COMBINED COEFFICIENT AND EXPANSION FACTOR CY AND REYNOLDS' NUMBER AND ACOUSTIC RATIO FOR A VENTURI TUBE

Combining equations where, as before,

$$P = P_1 - P_2 \text{ and } R = D_1/D_2 = \sqrt{r} \quad \ldots\ldots [64]$$

$$Q_1 = CY_1A_2\sqrt{\frac{R^4}{R^4-1}}\sqrt{2P/W_1} \quad \ldots\ldots [65]$$

or

$$Q_1 = CY_1\frac{1}{\sqrt{R^4-1}}A_1\sqrt{2P/W_1} \quad \ldots\ldots [66]$$

which are seen to be merely forms of the basic hydraulic equation with an added correction Y_1 for expansion.

$$Y_1 = \left[\frac{\left(\frac{1}{1-P_2/P_1}\right)\left(\frac{n}{n-1}\right)\left[1-(P_2/P_1)^{\frac{n-1}{n}}\right](P_2/P_1)^{2/n}}{\frac{R^4-(P_2/P_1)^{2/n}}{R^4-1}}\right]^{1/2} \quad \ldots\ldots [67]$$

If the throat conditions were used as a basis for the expansion factor Y_2, there would be considerably less correction for any given value of P_2/P_1. In other words, a higher differential can be used at a certain pressure with less expansion correction

than where the inlet conditions are used. However, it will be found in practice that the upstream conditions are actually more satisfactory for the expansion correction basis, since the upstream pressure P_1, which also affects the meter reading, is usually more nearly constant, and the combined effect of the density change and expansion correction is a minimum.

The combined coefficient and expansion correction factor must be a function both of the acoustic-velocity ratio and the Reynolds number when considered rigorously (see Fig. 7).[11]

VI—ORIFICE ANALYSIS

Orifice Considered as a Nozzle. As with the venturi tube, the theory for the orifice may be analyzed further to make clear the nature of the relations involved, and especially to permit the use of data obtained on one fluid for metering another fluid.

Expansion of the fluid affects the size of the *vena contracta* as well as the density of the fluid at the *vena contracta*. If the orifice is considered as a nozzle having its upstream and *vena contracta* corresponding to the inlet and throat connections, it is possible to obtain interesting information.

This method of consideration is correct for orifices having either "throat" connections, as above, or "flange" connections—which have nearly identical relations existing between quantity-rate of flow and differential pressure.[12]

The basic formula for gaseous fluids is

$$Q_1 = KA_1\sqrt{P/W_1} \quad \ldots\ldots\ldots\ldots\ldots [68]$$

as before, where K is the experimentally determined factor. This factor K includes the friction coefficient, contraction coefficient, and the combined correction for velocity of approach, including change of density from the inlet to the throat. (This factor depends both upon the Reynolds number and the acoustic-velocity ratio.)

Considering the orifice as a nozzle, it will be seen that the area of the *vena contracta* corresponds truly to the area of the throat at the nozzle. Experiments on orifices in glass pipes have established definitely the size of the *vena contracta* and consequently it has been possible (R-12*a*) to obtain the friction coefficient C_v as with a nozzle. This value has been found to be quite close to 0.97 for the usual sizes of orifice and ratios of orifice size to pipe size. The coefficient of contraction C_c has the expected value of approximately 0.61, depending somewhat upon the orifice ratio and the method of making pressure connections. The correction for compressibility and also the velocity of approach are exactly the same as would be expected with an ordinary nozzle. For purposes of determining this expansion Y_1 for the usual orifice ratios, it is merely necessary to divide the diameter of the orifice by $\sqrt{1.59}$ (= 1.26) in determining the ratio of diameters of the pipe and *vena contracta* for use in obtaining the adiabatic expansion factor Y_c.

The usual nozzle formula and coefficient may be used in determining the value of the compressibility factor and the *vena contracta*, assuming the friction coefficient C_v to be 0.97.

The "orifice" formula thus becomes

$$Q_1 = C_vC_cY_c\frac{1}{\sqrt{R_c^4 - 1}}A_1\sqrt{2gH_1} \quad \ldots\ldots\ldots [69]$$

the notation used being as follows:

Symbol	Dimension	Unit	Quantity
Q_1	L^3/T	cu. ft. per sec.	volume-discharge rate
C_v	....	0.97 (approx.)	friction coefficient
C_c	....	.....	contraction coefficient
Y_c	....	.....	adiabatic-expansion correction, (based on P_1) and diameter at *vena contracta*
$R_c = \frac{D_1}{D_c}$ ..... [70]			$\frac{\text{diameter at upstream (pipe)}}{\text{diameter at } vena\ contracta}$
D_c	L	ft.	diameter at *vena contracta* $D_c = \frac{D_2}{1.26}$ for computing Y_c
D_1	L	ft.	diameter of pipe
D_2	L	ft.	diameter of orifice
A_1	L^2	sq. ft.	area at upstream (pipe)
g	L/T^2	ft. per sec.^{2}	acceleration of gravity (32.174)
H_1	L	ft.	differential head of fluid itself at density W_1
W_1	M/L^3	lb. per cu. ft.	density at upstream conditions.

Consider an orifice having d_2/d_1 = nearly 0, measuring air. Then, for

P_2/P_1 =	1.0	0.90	0.80	0.70	0.60
x =	0.0	0.1	0.2	0.3	0.4
x/n =	0.0	0.071	0.142	0.213	0.284
$C_vC_cY_c$ =	0.597	0.584	0.569	0.552	0.533
$C_vC_cY_c/0.597$ =	1.000	0.978	0.953	0.924	0.893
Y_c =	1.000	0.944	0.887	0.825	0.758
C_c =	0.616	0.638	0.661	0.690	0.725
$C_c/0.616$ =	1.000	1.036	1.073	1.121	1.178

The increase of the *vena contracta* with the pressure differential is quite clear.

Consider another orifice where d_2/d_1 = 0.55 and d_c/d_1 = 0.55/1.26 = 0.437. Then, for

P_2/P_1 =	1.0	0.95	0.90	0.85	0.80
x =	0.0	0.05	0.10	0.15	0.20
x/n =	0.0	0.0355	0.071	0.107	0.142
$C_vC_cY_c$ =	0.608	0.601	0.593	0.585	0.576
$C_vC_cY_c/0.608$ =	1.000	0.988	0.975	0.962	0.948
Y_c =	1.000	0.9725	0.944	0.9135	0.883
C_c =	0.627	0.638	0.648	0.660	0.672
$C_c/0.627$ =	1.000	1.017	1.033	1.053	1.072

The increase of the *vena contracta* coefficient C_c for a gas referred to the corresponding coefficient for a liquid (same as gas at low differentials) 0.616 and 0.627, above, is seen to be substantially the same for both orifice ratios. Incidentally, the contraction coefficient is also a function of the Reynolds number and the acoustic ratio, and so is affected by a change in the ratio of specific heats as well as the pressure ratio.

Fig. 8 shows the results of this analysis graphically.

Vena Contracta and Reynolds' Number. Fig. 9 shows the combined effects of viscosity and expansion on the combined orifice coefficient and expansion factor. Although the expansion correction has been extrapolated equally at small and large Reynolds' numbers, the lines are dotted for streamline flow with

---

[11] These curves are based on the approximation that the corrections for viscosity and expansibility may be applied separately without appreciable error. Actually there will be a slight additional effect of expansion on the coefficient itself.

[12] However, this method of analysis is not so useful for orifices having "pipe" connections, 2½ pipe diameters upstream and 8 diameters downstream, since other factors affect the differential than in the case of a nozzle, especially the loss due to pipe friction and recovery of head following Borda's relation.

When "flange connections" are used having the orifice pressure connections close to the orifice itself, the pressures will correspond very closely with those at one pipe diameter upstream and at the *vena contracta*, and consequently the pressure corrections must be the same as though the pressure connections were as the pressures indicate, i.e., practically the same as with the "throat" connections.

For another type of connection ("pipe connections") sometimes used, which has the pressure connections 2½ pipe diameters upstream and 8 pipe diameters downstream, the use of the conditions at the upstream pressure connections is essential since the conditions at the downstream connection are practically indeterminate. In this case the pressure differential does not correspond with that at the point of maximum constriction, but is merely that due to an obstruction, and dissipation of energy occurs in which the expansion is not adiabatic, nor strictly anything else, as there is considerable effect of pipe friction included.

gases on account of the lack of direct data, also the increase of the *vena contracta* due to viscosity may have an effect upon its increase due to gaseous expansion.

The fluid in the center of the pipe passes through the orifice with considerable longitudinal acceleration, but without transverse deflection. However, the fluid near the wall of the pipe must be deflected radially inward toward the center to pass through the orifice opening, and in doing so acquires transverse momentum. Consequently, in the plane of the orifice itself the fluid near the edge of the orifice is moving toward the center as well as longitudinally at an angle Z which depends primarily upon the velocity distribution in the pipe for any given orifice ratio, i.e., the ratio of the velocity of the "obstructed" flow near the wall of the pipe to that in the center.

At large Reynolds' numbers with smooth pipe, the velocity

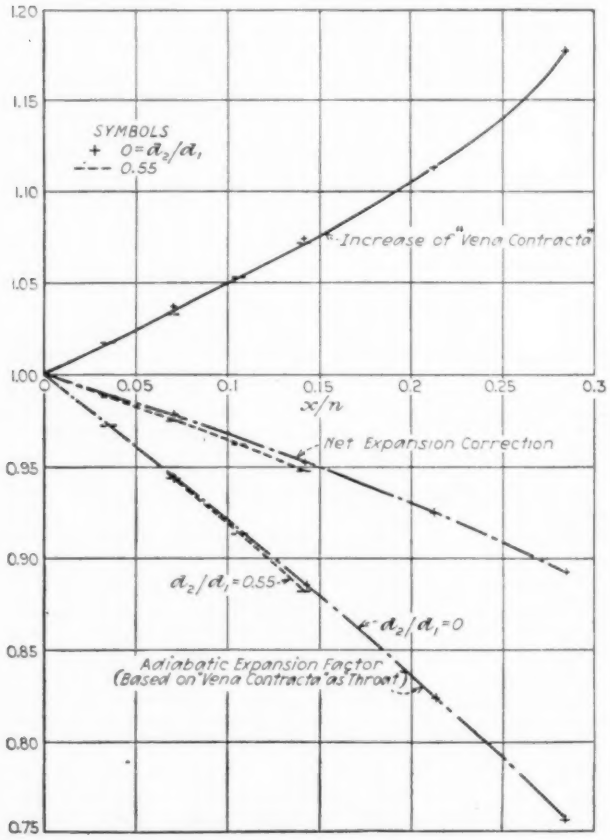

FIG. 8 VARIATION OF EXPANSION OF "VENA CONTRACTA," CONTRACTION COEFFICIENT C_c, AND ADIABATIC EXPANSION FACTOR Y_c FOR ACOUSTIC RATIO x/n FOR ORIFICES
(Data from U. S. Bur. of Stds. R.P.49.)

of the fluid near the walls of the pipe approaches the central velocity more nearly than at low Reynolds' number, the ratio of mean velocity to central velocity approaching a steady value of about 0.82 (see Appendix No. 3 on the "Flow of Fluids in Pipes"). (This is shown by the solid lines in Fig. 3.) The accompanying increased inward momentum causes the angle Z to be larger at high Reynolds' numbers than at low. With streamline flow the viscous friction of the fluid near the upstream face of the orifice itself tends to decrease the inward momentum and consequently the angle Z in addition to the above effect, until finally, at very low Reynolds' numbers the angle Z is negligibly small.

This type of flow at very low Reynolds' numbers is shown by the dot-dash lines in Fig. 3. For both high and low Reynolds' numbers the fluid between the stream and the pipe wall is practically stationary. The streamlines are *not* symmetrical on the upstream and downstream sides of the orifice, as is sometimes fallaciously assumed by mathematicians in theoretical analyses.

Downstream from the orifice, the stream contracts, when the angle Z is appreciable, until the section of maximum constriction or *vena contracta* is reached. There the velocity is nearly uni-

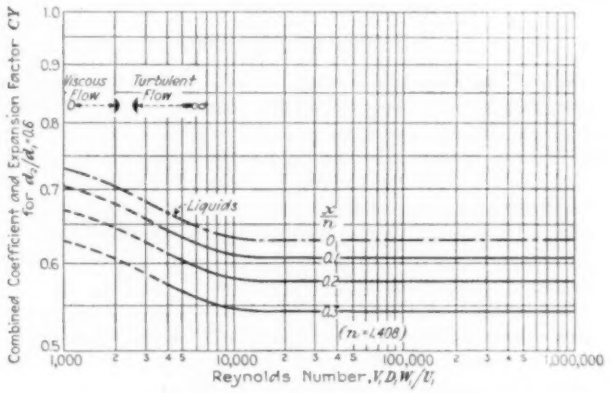

FIG. 9 RELATION BETWEEN COMBINED COEFFICIENT AND EXPANSION FACTOR CY AND REYNOLDS' NUMBER AND ACOUSTIC RATIO FOR AN ORIFICE

form and parallel and the ideal simple relation (that force equals mass times acceleration) is practically realized. The fluid between the stream and the wall of the pipe is in the "lee" of the orifice, and the only motion there is due to the relatively slight viscous drag of the stream. The motion of this fluid is generally sufficiently slow so that only slight effects occur due to its momentum.

The fluid in the stream at the downstream edge of the orifice at the plane of the orifice has practically the same pressure as at the *vena contracta*. However, the pressure in the center is in excess of that at the edge and, by the law of conservation of energy, the velocity in the center is less than that at the outside. It is this radial difference of pressure, and consequently density with gaseous fluids, which causes the *vena contracta* to increase for gases with the decrease of the downstream pressure (due to an increase of differential). With some shapes of differential producers, a serious deviation from "square-rootness" may occur with expansible fluids.

After the *vena contracta* is passed, the pressure increases and the stream fills the pipe as in the recovery cone of a venturi tube, but much less efficiently since more energy is lost due to eddy formation. The viscous drag of the quiet fluid in the "lee" of the orifice slows down the edge of the stream, turning it outward, and causing it to form the recovery "cone" as above.

The basic relations which govern the flow lines in the stream along the pipe are as follows:

1 The longitudinal forces, which are tangential with respect to the longitudinal profile of the boundary of the stream, depend primarily upon the acceleration from one section to another further downstream. This is primarily a function of the change of area of the sections.

2 The radial forces, with respect to the longitudinal profile of the boundary of the stream, depend upon the centrifugal law, which is that the radial force is proportional to the square of the velocity divided by the radius of the longitudinal profile of the boundary of the stream.

In other words, the longitudinal forces vary directly with the rate of change of the velocity with respect to time (depending

primarily upon the cross-sectional areas of the stream), while the radial forces vary directly with the square of the velocity divided by the radius of the longitudinal profile of the stream. Where the effects of viscosity are negligible, the ratio of these forces, and consequently the flow lines at the *vena contracta*, become highly stable, giving a constant or "flat" coefficient of contraction.

The overpowering effect of the large longitudinal acceleration generally wipes out the transverse momentum and thus produces streamline flow at the throat or *vena contracta*. The streamlines in the contracting section from the inlet to the *vena contracta* are very well defined for the usual ratios of orifice to pipe diameters, and the coefficient is stably defined by a single-valued function for the usual case where the approach is a straight

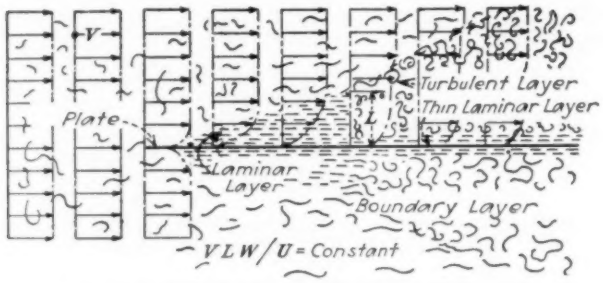

FIG. 10 TYPICAL BOUNDARY-LAYER PHENOMENA

length of smooth circular pipe with the velocity distribution and turbulence (flow similarity) definitely related to the Reynolds number.

Visual observation of flow of fluid in the glass pipes, using particles, dye streams, and "clouds" of dye, shows clearly that the flow near an orifice goes forward and inward at all points upstream of the orifice. This is contrary to the common assumption that there is a fixed eddy in the corner of the pipe and orifice just upstream of the orifice. It is surprising to notice how extremely slow and generally indeterminate the flow is in the "lee" of the orifice at moderate Reynolds' numbers for the observer who seeks order in physical phenomena.

The use of "streamlines" may seem a misnomer for describing highly turbulent flow through an orifice. For practical convenience, "dynamic streamlines" may be defined by stipulating that there must be zero net exchange of transverse momentum across such a line. So defined, dynamic streamlines may be useful in making the velocity-energy analysis necessary for the rational design of draft tubes, spillways, etc., in which the relation between quantity discharge and pressure differential must be estimated accurately. Here again, the best results may generally be obtained by taking full advantage of simple graphical methods, as opposed to complicated mathematical formulas.

The contraction for a parallel slot in an infinite plane has been theoretically determined for a non-viscous fluid. However, the mathematics is prohibitive in even the simple case of a circular orifice in an infinitely large thin plate. Consequently, since the mathematical difficulty of formal hydrodynamics is so great that even such simple physical cases are impracticable of solution, hydraulic engineers generally find it most profitable to make use of only enough of the theoretical mathematical analysis to obtain a clear picture of the physical phenomena involved, and then obtain the necessary information on the laws of flow from actual experiments and visual observation.

Coefficient for Low Pressure Ratios. When P_2/P_1 is low, say, below 0.25, the ratio P_1/Q_1 becomes constant (R-8), as in Napier's law; that is, the mass discharge becomes proportional to the upstream pressure as in the case of a shaped nozzle. If this constant is assumed to hold right down to the limiting value $P_1/P_2 = 0$, one may obtain, as follows, an equation which enables the curve relating the coefficient and expansion factor CY with P_2/P_1 to be extended down to zero P_2/P_1:

If

$$Q_w = P_1/E \quad \ldots\ldots [71]$$

where E is the experimentally determined constant value as above, then, using the basic hydraulic formula

$$Q_w = P_1/E = CYM\sqrt{2\,(P_1 - P_2)\,W_1} \quad \ldots\ldots [72]$$

or

$$CY = \frac{P_1}{EM\sqrt{2(P_1 - P_2)W_1}} = \frac{1}{EM\sqrt{2}} \frac{1}{\sqrt{\left(\frac{P_1}{P_1} - \frac{P_2}{P_1}\right)\frac{W_1}{P_1}}} \quad \ldots [73]$$

whence

$$CY = \frac{1}{EM\sqrt{2}} \frac{1}{\left(1 - \frac{P_2}{P_1}\right)\sqrt{1/R'T_1}} \quad \ldots\ldots [74]$$

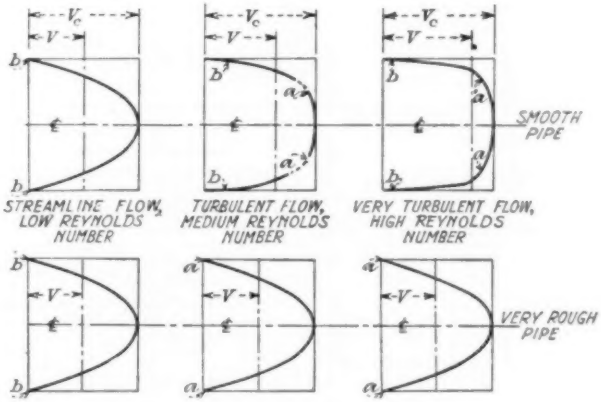

FIG. 11 DIAGRAM OF VELOCITY DISTRIBUTION FOR FLOW IN STRAIGHT CIRCULAR PIPES

where R' and T_1 are from the basic gas density relation $W_1 = P_1/R'T_1$.

$$CY = \frac{1}{EM}\sqrt{\frac{R'T_1}{2}} \frac{1}{\sqrt{1 - \frac{P_2}{P_1}}} \quad \ldots\ldots [75]$$

and in the limit where $P_2 = 0$,

$$CY = \frac{1}{EM}\sqrt{\frac{R'T_1}{2}} \quad \ldots\ldots [76]$$

A_1	L^2	sq. ft.	area of upstream section
$C = f_1(R_1)$	.....		coefficient, correcting for shape and viscosity
$Y = f_2(R_{a1})$	.....		expansion factor, correcting for shape and expansion

Straight-Line Expansion Formula

$y = 1 - Y$ [5]; $y = bx/n$ [6]			"straight-line" expansion correction
b			"straight-line" expansion constant depending upon shape

$H = V^2/2g = P/gW$

H	L	ft.	differential head of fluid acting against gravity
g	L/T^2	ft. per sec.^{2}	acceleration of gravity (32.174)

Basic General Formula

$$Q_1 = kD_1^2 \sqrt{P_1 W_1} \quad \ldots\ldots [9]$$

or

$$Q_1 = kD_1^2 \sqrt{gH_1} \quad \ldots\ldots [10]$$

Q_1	L^3/T	cu. ft. per sec.	volume-discharge rate (at upstream density)

Acoustic-Velocity Formula

$$V_a = \sqrt{nP_1/W_1} \quad \ldots\ldots [18]$$

Open-Channel Factor (Froude's Ratio)

$$2gL'/V^2 \quad \ldots\ldots [41]$$

L'	L	ft.	depth (or other dimension) of channel

Venturi-Meter-Coefficient Formula (From Bernoulli's Theory)

$$C = \sqrt{\frac{R^4 - 1}{\alpha_2 R^4 - \alpha_1 + b}} \quad \ldots\ldots [50]$$

where $R = D_1/D_2$

Venturi-Meter Expansion-Factor Formula (From St. Venant's Theory)

$$Y = \left[\frac{\frac{1}{1 - M} \frac{n}{n - 1} \left(1 - M^{(n-1)/n}\right) M^{2/n}}{\frac{R^4 - M^{2/n}}{R^4 - 1}} \right]^{1/2} \quad \ldots [67]$$

where $M = P_2/P_1$ and n = specific-heat ratio.

Orifice Formula (Based on *Vena Contracta* as Throat of Corresponding Nozzle)

$$Q_1 = C_v C_c Y_c \frac{A_1}{\sqrt{R_c^4 - 1}} \sqrt{2gH} \quad [69]$$

(subscript c indicates conditions at *vena contracta*)

C_v	= 0.97 approximately	friction coefficient
C_c	$= Ac/A_2$	contraction coefficient
Y_c		expansion factor, adiabatic expansion assumed from upstream 1 to *vena contracta* c
R_c	$= D_1/D_c$	

Orifice Formula (From Napier's Law)

$$Q_w = P_1/E = CY k_3 \sqrt{2(P_1 - P_2)W_1} \quad \ldots\ldots [72]$$

$$CY = \frac{1}{Ek_3} \sqrt{\frac{R'T_1}{2}} \quad \ldots\ldots [76]$$

where $P_2 = 0$, (R' from $W = P/R'T_1$)

Pipe-Friction Formula

$$H = K \frac{L}{D} \frac{V^2}{2g} \quad \ldots\ldots [80]$$

where $K = f(VDW/U)$

Appendix No. 2

NOTES ON VISCOSITY, AND AN INTRODUCTION TO THE LAW OF DIMENSIONAL HOMOGENEITY

VISCOSITY is a measure of the internal friction of a fluid. It appears as a force which tends to drag a surface in a moving stream of fluid along with the stream.

The absolute viscosity of a fluid is defined as the tangential dragging force exerted, per unit of area, on one plane by a fluid between two parallel planes (which are immersed in the fluid at a unit distance apart) when one plane moves parallel to the other with unit relative velocity, without rotation.

The dimensions of viscosity U are M/LT or $ML^{-1}T^{-1}$. In c.g.s. units this would be grams per centimeter second (gr./cm. sec.) and in absolute f.p.s. units would be pounds per foot second (lb./ft. sec.).[13]

In order to express this relation by formula, the flow must take place as follows:

1 The fluid must not "slip" at the surfaces, i.e., the fluid adhering to the plane must have zero velocity relative to the surface.

2 All the fluid motion must be streamline only, parallel to the direction of motion of the planes and without any eddying or turbulence.

3 The resistance to flow must be directly proportional to the rate of shear.

4 The resistance to flow must be proportional to the area of the surface.

True fluids meet these conditions at sufficiently low rates of shear. Viscosity is due to the interchange of momentum between molecules passing from one layer of fluid to an adjacent layer moving with a different velocity. The faster-moving molecules upon passing into the slower-moving layer of liquid increase its velocity in the direction of flow, and vice versa, the net tendency being to equalize velocities throughout the fluid, i.e., to resist shear.

This interchange of momentum obviously depends directly upon the difference in the velocities in adjacent layers—the rate of shear—and also with the area of the surface.

Where, as above, the following notation is employed:

Symbol	Dimension	Unit	Quantity
..	M	gram	mass
..	L	cm.	length
..	T	sec.	time
D	L	cm.	distance between two parallel planes
A	L^2	sq. cm.	area of each plane
V	L/T	cm. per sec.	tangential relative velocity
F	ML/T^2	gram-cm. per sec.^{2}	tangential force acting
U	M/LT	gram per cm-sec.	viscosity of the fluid
$F = UAV/D$		or in words,	

[13] The gram and pound are mass dimensions, as indicated by the use of M above.

the tangential force F acting is directly proportional to the viscosity U, area A, and rate of shear V/D.

$$U = FD/AV$$

and as the dimensions on each side of an equation must be equal, the dimensions of viscosity are

$$\left(\frac{ML}{T^2} \times L\right) \Big/ \left(L^2 \times \frac{L}{T}\right) = \frac{ML^2T}{L^3T^2} = \frac{M}{LT} \quad \text{[77]}$$

as above.

When in c.g.s. units, the unit for the viscosity is sometimes known as the "poise" after Poiseuille who first determined the absolute viscosities of various liquids; the corresponding unit in f.p.s. units has similarly been termed the "poisel." However, the fundamental units of gram per cm-sec. and lb. per ft-sec. must be adhered to, in order to prevent confusing engineers who do not have constant use for these values.

It is interesting to note here that the viscosity of water at about 68 deg. fahr. is almost exactly 0.010 gram per cm-sec., and thus the convenient value of this unit, termed the "centipoise," is in common use.

The kinematic viscosity ν is the ratio of the absolute viscosity U to the density, W, or is equal to U/W, where

U	M/LT	gr. per cm-sec.	viscosity
W	M/L^3	gr. per cu. cm.	density
ν	L^2/T	sq. cm. per sec.	kinematic viscosity

since for U/W,

$$\left(\frac{M}{LT}\right) \Big/ \left(\frac{M}{L^3}\right) = \frac{L^2}{T} \text{ [i.e., sq. cm. per sec.]} \quad \text{[78]}$$

The kinematic viscosity may be obtained from the number of seconds that it takes a standard quantity of oil to flow from a standard viscosimeter (such as 60 cu. cm. with the Saybolt Universal viscosimeter) and referring to a conversion graph or table.

Since the density of water at 68 deg. fahr. is close to unity, the kinematic viscosity in c.g.s. units of water is approximately 0.010/-1.00 = 0.010 sq. cm. per sec., and the specific kinematic viscosity based on water at 60 deg. fahr. (ν = 0.0113 sq. cm. per sec.) may be convenient in oil calculations where coefficients, based on water at 60 deg. fahr., are available, this being frequently the case since the specific gravity based on 60 deg. fahr. is in common use, and this places the units on a common basis.

It is fortunate that American petroleum oils generally have an approximately straight-line logarithmic relation between kinematic viscosity and temperature which permits the kinematic viscosity to be determined at any temperature (not too low) closely enough for commercial metering, by merely plotting upon logarithmic paper several kinematic viscosities obtained at several temperatures, say, from the Saybolt Universal viscosimeter, and drawing a line through them. Most oils at low temperatures form semi-solids. This type of oil can best be metered after raising its temperature until it becomes a true fluid, having a determinable viscosity.

Notes on Viscosity

Gases. The viscosity of a gas increases with the absolute temperature, but is practically independent of pressure. This naturally follows from the concepts that viscosity is due to the interchange of energy between molecules, and that the velocity of gas molecules increases with the absolute temperature.

For perfect gases, in which the particles repel each other as the nth power of the absolute temperature, the absolute viscosity U is

$$U = k\left(\frac{n+3}{2n-2}\right) \quad \text{[79]}$$

When $n = 5$, it will be seen that the viscosity is directly proportional to the absolute temperature.

Liquids. It is interesting to note that although the viscosity of gases increases with an increase of absolute temperature, still the viscosities of liquids generally decrease with an increase of absolute temperature.

Oils. For usual petroleum oils there is a slight increase of viscosity at very high pressures, still the viscosity may be considered as being practically independent of pressure, just as the density is considered practically constant—i.e., liquids are generally considered to be incompressible in ordinary hydraulics. The primary reason why the viscosity of oils decreases with an increase of temperature is that, when the temperature increases, the molecules are more widely separated and consequently there is less interchange of momentum between molecules. It is merely a fortunate physical coincidence that permits an approximately straight-line relationship between the logarithm of absolute viscosity (and the kinematic viscosity as well) and the logarithm of the temperature in degrees fahrenheit.

Appendix No. 3

FLOW OF FLUIDS IN PIPES

SINCE the usual fluid meters are installed in circular pipes, which are more or less rough, it is profitable to note the phenomena which ordinarily prevail, i.e., the relation between turbulence (flow similarity), the friction constant, and the Reynolds number. The pressure drop for actual fluids having finite viscosity, along a length of pipe, is a function of the shape factor (including roughness), and the Reynolds number, VDW/U.

The usual formula expressing the relation between pressure loss in a straight circular pipe and the friction factor, is conventionally derived by equating dimensional exponents. The formula is as follows:

$$H = K\frac{L}{D}\frac{V^2}{2g} \quad \text{[80]}$$

where $K = f(VDW/U)$.

Data illustrating the relation between the friction factor K and the Reynolds number (R-13) for smooth pipe appears on the graph, Fig. 1. The effect of roughness is practically negligible in the streamline régime, but has considerable effect in determining the critical velocities and the friction factor K in the turbulent régime. There is a definite but not highly stable régime between the streamline and turbulent which may well be termed the "superturbulent" régime, since the pressure loss varies approximately as the third power of the velocity there, while in the streamline régime it varies as the first (1.0) power of the velocity and in the turbulent régime usually varies as some power between the 1.75 and the 2.0 power of the velocity.

Conventional Derivation of Reynolds' Number

Assuming that the elasticity of the fluid does not appreciably affect the flow and that a steady flow state exists, the independent related quantities for flow through a differential producer of a certain shape must be as follows:

P	M/LT^2	pressure differential
D	L	diameter of main pipe
V	L/T	velocity of flow in pipe
W	M/L^3	density of fluid, and
U	M/LT	viscosity of fluid
Q	L^3/T	quantity-rate of flow, dependent upon D and V.

Consider any term in an expression for pressure differential; its dimensions must be those of pressure differential.

$$P = kV^wD^xW^yU^z \quad \text{[81]}$$

$$ML^{-1}T^{-2} = (LT^{-1})^w L^x (ML^{-3})^y (ML^{-1}T^{-1})^z \quad \text{[82]}$$

$$= M^{(y+z)} L^{(w+x-3y-z)} T^{(-w-z)}$$

Hence

for T, $2 = w + z$ [83]

for M, $1 = y + z$ [84]

for L, $-1 = w + x - 3y - z$ [85]

and therefore

$$w = 2 - z \quad \text{[86]}$$

$$y = 1 - z \quad \text{[87]}$$

$$x = -z \quad \text{[88]}$$

and each term is of the form

$$P = kV^{2-z}D^{-z}W^{1-z}U^z \quad \text{[89]}$$

$$P = kWV^2(VDW/U)^{-z} \text{ and } VDW/U = R \quad \text{[90]}$$

where the Reynolds number is R, however,

$$Q = 0.7854D^2V \quad \text{[91]}$$

and so

$$P = k_1WQ^2/D^4 \quad \text{[92]}$$

where $k_1 = f_1(R)$, and

$$Q = K_1D^2\sqrt{P/W} \quad \text{[93]}$$

where $K_1 = F(R)$.

K_1 and the corresponding values of the Reynolds number R may be determined from experiment. Thus the coefficient for a differential producer in a closed conduit is found to depend only upon the Reynolds number under the conditions stated above.

For one pipe-diameter length of straight pipe

$$P = K_1 W V^2 \quad [94]$$

where $K_1 = f_1(R)$, and for a length L of pipe (L/D pipe diameters long),

$$P = K_2 W V^2 \frac{L}{D} f_1(R) \quad [95]$$

In hydraulic work, this law is ordinarily expressed in head H of the liquid itself, or

$$H = K \frac{V^2 L}{2gD} \quad [96]$$

where $K = f(R)$.

Regarding the negative exponent for Reynolds' number, the departure of the coefficient from its "flat value," which is generally of primary interest, is due fundamentally to viscosity. The inverse of the Reynolds number is directly proportional to the viscosity, and so this inverse is generally more significant physically than the number itself. In the derivation of fluid-flow expressions, it will generally be found that the inverse of the number appears in the final expression. However, in view of its historical background and the familiarity of the Reynolds number, it is retained in this work.

PHYSICAL DESCRIPTION OF FLOW PHENOMENA

Flat Plate Moving Through Still Fluid (see Figs. 10 and 11). The modern idea of flow of fluids in pipes is based upon the recognition of the existence of a "boundary layer" next to any surface immersed in the fluid and is somewhat as follows: For simplicity, let us consider the flow past an infinitely thin flat plate mounted rigidly in a fluid moving uniformly in a direction parallel to the plate. There can be no finite slip at the wall, hence the fluid in immediate contact with the plate has zero velocity. As we pass outward into the body of the fluid perpendicularly to the plate, the velocity increases rapidly, but with an ever-decreasing rate of change of velocity, approaching asymptotically the velocity V of the undisturbed stream. Owing to the fact that the velocity V is approached asymptotically as we move outward from the plate, we cannot set an arbitrary limit to it except by defining its thickness as that distance at which the velocity has a value less than that of the stream ahead of the plate by some small fixed amount.

It is considered that this boundary layer is infinitely thin at the leading edge of the plate. It increases in thickness as we pass toward the rear edge of the plate, according to a definite law which is fairly well established. The flow in this layer is laminar as far as we have yet considered it, while the flow in the stream is turbulent. This turbulent flow in the undisturbed mass of fluid sets up forced vibrations in the laminar layer which, since it becomes thicker as we pass toward the rear of the plate, becomes more and more responsive to these impulses which are due to turbulence in the fluid outside. Finally, at a particular value of Reynolds' number (in which the linear dimension L is the thickness of the layer) the laminar flow in the boundary layer breaks down and becomes turbulent. The vortex sheet sometimes observed at the wall of a ship is one of the more obvious phenomena occurring in the turbulent part of the boundary layer.

As regards the relative turbulence in the boundary layer and outside of it, it is known that in the turbulent portion of the boundary layer, the turbulence is much greater than in the outside fluid. It is undoubtedly true that the turbulence (due to the forced vibration) in the laminar portion of the boundary layer is less than in the fluid outside but there is no definite data at hand on this subject.

Since the boundary layer increases in thickness as we pass from the leading edge, in the case of a plate or from the entrance of a pipe, it is obvious that ultimately a pipe will be entirely filled with the boundary layer.

(In what is said in the last two paragraphs it should be noted that the "turbulence" due to forced vibration in the laminar portion of the boundary layer, is a sort of oscillation and not "eddying" as in what is ordinarily termed turbulence.)

The fact that there is a thin laminar layer at the wall of a pipe is borne out quite clearly from heat-transfer phenomena: in which the resistance to heat transfer decreases markedly as the turbulence in the pipe increases. Roughness, which strongly affects the friction loss in turbulent flow, has no appreciable effect upon purely streamline flow and consequently this laminar layer must be quite thin for the effect of roughness to penetrate into the turbulent flow. Also actual experimental data with a microscopic pitot tube (R-14) showed that streamline flow exists immediately adjacent to the walls of a pipe in the turbulent régime. Fluid flowing in a large conduit at any reasonably high velocity must have turbulent flow existing throughout its body, since turbulence depends fundamentally upon the ratio of transverse to longitudinal momentum. Where the flow of the body of the fluid is parallel to a surface, the transverse momentum is necessarily suppressed at the surface itself, producing a thin lamina of streamline flow at the surface. The fundamental difference between streamline and turbulent flow follows from the fact that there is no transverse momentum, other than on a molecular scale, found in the streamline régime. This fact lends added weight to the modern conception of the existence of the "boundary layer" of laminar flow where a thin sheet of fluid flows in streamlines parallel to the surface.

There is a fundamental difference in the law of flow between the movement of a flat surface through a body of "still" fluid, parallel to the surface, and the movement of relatively unconfined "flowing" fluid past the same surface. The resistance to the motion of a vessel through quiet water is affected appreciably by the viscosity of the water. Tests on very large conduits containing highly turbulent flow (with large Reynolds' numbers) on the other hand, have the resistance follow practically the square of the velocity—in which case viscosity naturally has practically negligible effect. The viscous frictional resistance for a ship is due somewhat to the viscous drag of previously still water in the ship's direction of motion. The large conduit, on the contrary, is practically completely filled with the highly turbulent flow, and the viscous effect of laminar flow at the walls reaches a minimum.

The erroneous concept of how fluid flows in pipes, which was accepted popularly by hydraulic engineers, follows: For turbulent flow, it was assumed that the adhesion of the fluid next to the wall of the pipe broke (R-15), and that there was highly turbulent flow next to the wall of the pipe with substantially streamline flow in the center portion of the pipe. The fact that almost none of the usual closed conduits, with which hydraulic engineers are familiar, are transparent has permitted such a faulty, but apparently reasonable, conception to exist for many years among engineers who are well versed in making precise calculation of the pressure loss for various velocities, which being measurable quantities are consequently observable.

Velocity Distribution (Flow Similarity) and Reynolds' Number. For turbulent flow there is a fictitious "mechanical viscosity" which appears for any fluid in the center portion of a pipe, see Fig. 11. Parabolic velocity distribution exists in the center of the pipe from a to a. This viscosity depends only upon the Reynolds number. It is due to the fact that transverse momentum is transferred uniformly throughout the conduit in highly turbulent flow just as transverse momentum on a molecular scale is transferred uniformly throughout the body of the fluid in the streamline régime with laminar flow, which gives a parabolic velocity distribution from b to b.

[For a parabolic velocity distribution in a circular pipe, the "velocity head"

$$H_{v1} = V^2/g \quad [97]$$

and the mean velocity $V = 0.5\ V_c$ where V_c is the central velocity. With a venturi-tube throat for turbulent flow in the pipe, the velocity distribution is practically constant, and so the velocity head at the throat

$$H_{v2} = V^2/2g \quad [99]$$

and $V = V_c$; for turbulent flow in smooth pipe, $V/V_c = 0.5$ to 0.82; and so the velocity head $H_v = V^2/g$ to approximately $V^2/2g$. See Fig. 1 for the relation of V_1/V_c for smooth pipes data by Stanton.]

The velocity distribution is found experimentally to depend only on the Reynolds number for an extremely rough pipe. Parabolic velocity (a to a) distribution extends entirely to the wall of the pipe, whereas for ordinary relatively smooth pipe there is a boundary effect which extends inwardly from the walls of the pipe (to a) with the streamline laminar flow layer extending inwardly from the walls of the pipe to b, distances which diminish as the turbulence, as measured by the Reynolds number, increases.

The parabolic distribution of flow has become popularly associated with streamline flow whenever the value of the Reynolds number is less than Reynolds' critical-velocity value, which of course is true for smooth cylindrical pipes. However, at a venturi throat, or orifice *vena contracta*, there has been a powerful longitudinal acceleration which has practically wiped out all transverse momentum, thus producing true streamline flow. However, the velocity distribution is practically uniform across the throat or *vena contracta* under these conditions (absolutely *not* parabolic).

It has been observed that, with turbine nozzles, streamline flow

exists at much higher velocities than would be possible for flow in cylindrical pipes. Water issuing at high velocity from fire nozzles or Pelton turbine nozzles has the "glassy" appearance indicative of streamline flow. It has been erroneously assumed that since the flow in such a nozzle or venturi tube is streamline, there must be a parabolic velocity distribution. This conception has led to faulty estimates (R-16) of the value of the coefficient for the venturi tube. This important point is discussed here to emphasize the fact that the Reynolds number does absolutely not indicate the same velocity distribution across the throat of a venturi tube or *vena contracta* as it does in straight circular pipe, which constitutes another reason for using the physically significant Reynolds number with pipe diameter instead of throat diameter.

Similarity: Limitations in Its Application to Fluid Flow

By J. M. SPITZGLASS,[1] CHICAGO, ILL.

A brief resume of the development of the art for the purpose of bringing about a better understanding of the effects of hydraulic similarity as related to the geometrical similarity of the various devices. Geometrical similarity is of great importance, and devices which are geometrically similar will make the operation more uniform. Geometrical similarity is a matter of construction. Hydraulic similarity is a matter of experiment. Large sizes may or may not show the same results as the smaller ones.

THREE stages are apparent in the usual analysis of physical phenomena. The first stage is reached when preliminary observations or discoveries give sufficient data to form a hypothesis and to warrant further investigation. The second stage is reached when the hypothesis has been applied to a number of cases, and the results warrant the formation of a theory or a workable formula. The third stage is when the theory is shown to hold under all known conditions. Then it is proved and becomes a law.

Physical laws are seldom directly workable. They are true only for abstract or ideal conditions. They are limited to the literal fulfilment of the "ideal" requirements, embodied in the statement of the given law. In other words, we have no conception, except in the abstract, of a case where a given "law" could be applied independently without the interference of other similar or dissimilar laws. In reality, physical relations of quantity are subject only to working hypotheses or theories expressed in given formulas or mathematical equations. These formulas usually are made up from corresponding sets of assumptions based upon some visible or apparent influences and expectations.

On the other hand, any set of well-defined assumptions establishes a "mathematical" relation which in the working process of determining numerical quantities has the same status as any other given set of assumptions applicable to the same case. The difference, then, between the two sets is only a mathematical quantity or ratio. By means of this ratio one set may be converted into the other. Either set may be a law or both sets may be only assumptions; the mathematical relation between the two remains the same.

Let us apply this "law" to the case at hand, the flow of fluid through similar pipes and orifices.

Hydraulic-Flow Equations

There has been a good deal of mathematical genius displayed in the development of fluid-flow equations. A multitude of formulas have been advanced, both rational, based on general assumptions, and empirical, based on a limited amount of experimental data. For our demonstration it will be sufficient to take three or four rational forms that have been thus far accepted as working bases.

The first equation was created by Torricelli (1)[2] in 1643 when he discovered that the velocity of a water jet issuing from an opening in the side of a reservoir was "nearly" the same as that which would be acquired by a heavy body falling from the vertical height measured from the surface of the water in the reservoir to the center of the opening where the jet leaves the reservoir.

This discovery gave rise to the equation

$$V = C\sqrt{2gh} \qquad [1]$$

which is based upon the law of falling bodies. If we use the letter p to denote the equivalent drop of pressure, then, since $gh = p/\gamma$ we have from [1],

$$V = C\sqrt{2p/\gamma} \qquad [2]$$

and

$$p = \frac{1}{2C^2} V^2\gamma \qquad [3]$$

As the science of hydrodynamics advanced after Torricelli's time, the early experimenters, like Edme Mariotte (2) and even Sir Isaac Newton (3), could not adequately explain the "contraction" of the jet after it leaves the opening in the reservoir. The first plausible explanation was advanced by the celebrated Danielis Bernoulli (5) in his famous "Hydrodynamica," published in Latin in 1738. Bernoulli discarded Newton's theory of moving and stationary parts in the reservoir or the so-called "waterfall" theory, and showed that the whole mass of the fluid moves toward the opening and that the resulting jet is determined by the state of equilibrium in the nature of that motion. Bernoulli's explanation of that phenomenon is claimed to be one of the most beautiful and the most artistic products of mathematics. Bernoulli's theory has brought to light other forces that come into play for establishing the state of equilibrium in the flowing stream.

It is of interest to note that the early experimenters have limited their activities to sharp-edged orifices and jets issuing from large tanks, and the fact that the orifice coefficient increases at low heads was observed by Bossut (6) before 1775. He explained that fact by the slight increase of contraction at higher heads due to the larger tangential force toward the center.

At the same time other experimenters [Couplet (4) being the first] were wondering how to express the drop of pressure in conduits where the velocity neither increased nor diminished, and how to reconcile that drop of pressure with the law of Torricelli.

It appears that around the year 1775 M. Chézy (7), director of the French school "des Ponts et Chausseés," was in charge of the Ivette canal construction and was endeavoring to obtain a formula for the relation between the slope of an aqueduct, the dimensions of its transverse section, and the amount of water it could supply in a given time.

Chézy assumed that when water moves in a given channel, the accelerating force of the slope is counterbalanced by the

Contributed by the Special Research Committee on Fluid Meters and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers. For discussion and author's closure, see pp. 123–135.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] A numeral after a name refers to the index of cited references at the end of the paper.

resistance the water overcomes in sliding along the walls of the channel. Then the resistance must be proportional to the surface in contact. Chézy also assumed that the resistance is proportional to the square of the mean velocity in the channel. With these assumptions he formed an equation of two terms, the first being the product of the slope by the cross-section of the channel (the accelerating force Ah/L); the second, the product of the wetted perimeter by the square of the velocity (the retarding force BV^2).

The assumption was that the term Ah/L must be proportional to BV^2. From his experiments on open channels Chézy obtained values for a coefficient that balanced the two terms. The work is on record in the manuscripts of the school "des Ponts et Chausseés."

The final form of the Chézy formula was

$$V = n\sqrt{rs} \quad \ldots\ldots [4]$$

in which V is the mean velocity of the fluid; r the mean hydraulic radius A/B, or ratio of the area to the wetted perimeter of the conduit; and s the hydraulic slope or the ratio h/L. For circular pipes $r = D/4$, so that

$$V = n\sqrt{\frac{D}{4} \times \frac{h}{L}} \quad \ldots\ldots [5]$$

Some of the writers, like Hamilton Smith (21), continued to make the coefficient n include the value of $\sqrt{2g}$, which they considered constant. This was really a disadvantage because the coefficient had different values for different systems of units. For our purpose we shall adopt the same form but not include the value of $2g$ in the coefficient. Thus

$$V = n\sqrt{\frac{D}{4L}}\sqrt{2gh} \quad \ldots\ldots [6]$$

and again replacing gh by p/γ, we have

$$V = n\sqrt{\frac{D}{4L}}\sqrt{2\frac{p}{\gamma}} \quad \ldots\ldots [7]$$

and

$$p = \left(\frac{1}{2n^2}\right)\left(\frac{4L}{D}\right)V^2\gamma \quad \ldots\ldots [8]$$

Note the similarity of Equations [7] and [8] and [2] and [3]. What does this mean? Is $n\sqrt{D/4L}$ of Equation [7] actually equal to C of Equation [2]? It is if we refer the two to the same experiment.

Let us illustrate by specific examples from the early experimenters. Couplet (4) in 1732, introducing his experiments on the flow of water in pipes, makes the following statement:

> We shall see by following our experiments that a conduit which according to the rules [of Mariotte] would have furnished 61 $^{11}/_{25}$ flowing inches of water, furnished only 2 inches and 63 lines because the conduit was extremely long, even though it was open mouthed as illustrated on the 4 inch pipe, Figure 1. . . . If the pipe were constructed according to the rules [of Mariotte] it would have been five times too small [in diameter] and would have supplied $^1/_{25}$ of 2 flowing inches and 63 lines.

Bossut (6) in 1775, the next experimenter, after giving in detail his and also M. Couplet's data, prepared a long table showing the relation between the delivery through the given length of pipe and the delivery through a short tube of the same diameter. So in both cases the scientists of that time tried to relate the flow in the pipe to the corresponding flow through a short tube or to Torricelli's equation.

In Bossut's table the ratio of pipe flow is actually a value for C in Equation [2]. His value of C for short tubes was approximately 0.815, and the given ratios varied from 3.18 in a short pipe to 28.5 in a long pipe. This ratio in itself has no meaning, but from the value of this ratio a solution may be obtained for n of Equation [7]. I found that in Bossut's experiments on 1-in., $1^1/_2$-in., and 2-in. diameter pipes n varied from a minimum of 11 to a maximum of 13, while in Couplet's experiments the value of n is from 4 to 5 in the 4-in. pipe, 8 to 9 in the 6-in. pipe, 9 to 11 in the 5-in. pipe, and 9 on one 18-in. pipe, and 13 on the other. This inequality caused Chevalier Dubuat (8) to retain only the data on the 5-in. pipe and one of the 18-in. for his demonstration.

What the similarity of the equations really means is this: Given a certain set of experimental data where a pressure difference and a velocity are involved, one may choose to assume conditions leading to Equation [2] and solve for C, or he may choose to assume conditions leading to Equation [7] and solve for n. As soon as a solution is obtained for either C or n, the shift from one set of assumptions to the other is subject only to the mathematical relation of C to n as obtained by reducing Equations [2] and [7] to one common denominator, or by shifting from Torricelli's assumptions to those of Chézy.

Chézy's formula was later modified to shift the coefficient from velocity to friction. The equation for friction drop in pipes then read:

$$f\frac{V^2}{2g} = \frac{h}{L}\frac{D}{4} \quad \ldots\ldots [9]$$

$$V = \sqrt{\frac{D}{4fL}}\sqrt{2gh} \quad \ldots\ldots [10]$$

$$V = \sqrt{\frac{D}{4fL}}\sqrt{2\frac{p}{\gamma}} \quad \ldots\ldots [11]$$

and

$$p = \left(\frac{f}{2}\right)\left(\frac{4L}{D}\right)V^2\gamma \quad \ldots\ldots [12]$$

The similarity of Equations [11] and [12] to [7] and [8] and to [2] and [3] is apparent. From these equations we have the following relations established between the three coefficients, provided we shift from one set of assumptions to the other for the same set of experimental data:

$$C = n\sqrt{\frac{D}{4L}} = \sqrt{\frac{D}{4fL}} \quad \ldots\ldots [13]$$

$$n = C\sqrt{\frac{4L}{D}} = \sqrt{\frac{1}{f}} \quad \ldots\ldots [14]$$

$$f = \frac{1}{C^2}\frac{D}{4L} = \frac{1}{n^2} \quad \ldots\ldots [15]$$

New Factors Appear

A contemporary of Chézy, the military engineer Chevalier Dubuat (8), was the first to observe a variation in the results with different sizes of conduit. Dubuat conducted a large number of laboratory experiments in 1781, 1782, and 1783 on both narrow and large tubes. His conclusions and the corresponding assumptions were more specific than those of Chézy. To quote from his introduction:

> It is evident that when water flows uniformly in any bed the accelerating force that maintains the flow is equal to the sum of the resistances which it forms, either by its own viscosity or by the friction of the bed. This law appeared to me as old as the rivers and it should form the key to hydrodynamics. It presents itself in an illuminating way, and it is in other respects the basic foundation of uniform motion.

Dubuat was also the first to use the term "viscosity" in this respect, and to vary the temperature of the water in his experiments. His empirical equation, however, contained only the elements of the Chézy formula and a logarithmic function to take care of the variation in the size of the tube. He included no function for temperature changes affecting the flow of the fluid.

Professor Gerstner (10), of the Prague University, experimented directly on the effect of temperature on the fluidity of liquids. His results, as published in the year 1800, showed that the temperature has a greater influence on small diameters and low velocities, and there is a remarkable reference in his article to the effect of heat on the flow of blood through the veins and arteries of the human body.

It is characteristic of that epoch that hydraulic investigations were a part and parcel of natural science, and that learned men in the field of physics and physiology took an active interest in hydraulics. In 1808 the physiologist, Thomas Young, M.D. (12), published an article under the title "Hydraulic Investigations Subservient to an Intended Croonian Lecture on the Motion of the Blood." The Croonian lecture by Dr. Young, published in 1809, was of a purely physiological nature, but the hydraulic investigations in 1808 disclosed a very able physicist and excellent mathematician.

Dr. Young, however, did not investigate the effect of temperature. Instead he adopted the formula advanced by Pierre Simon Girard (11), who, following the assumptions of Chézy and Dubuat and the principles advanced by Coulomb (9), concluded that the resistance to the flow of fluid in conduits was composed of two terms, one involving the first power and the other the square of the velocity. The equation, as given by Young, was in the form of

$$h = a\frac{L}{D}V^2 + 2b\frac{L}{D}V \quad \ldots\ldots [16]$$

Dr. Young rearranged the experiments of Bossut, Dubuat, and Gerstner in accordance with his formula (Equation [16]). Supplemented by his own tests he arrived at empirical values for a and b. These values were made functions of diameter in various powers.

Girard, at that time Engineer-in-Chief "des Ponts et Chausseés," was engaged in experimental work to establish the validity of his principle that the resistance to flow was a function of both the first and also the second power of the velocity. In 1813 Girard (13) submitted to the school "des Ponts et Chausseés" a classical piece of work on the subject of the flow of fluids in capillary tubes and the influence of temperature. From these experiments he showed that while in general the resistance to flow was a function of two terms, one involving the first power and the other the square of the velocity, yet in small, narrow tubes the value of the term involving the square of the velocity was insignificant and the function was reduced to the term involving only the first power of the velocity. Girard's general equation for circular pipes was

$$aV + bV^2 = g\frac{D}{4}\frac{h}{L} \quad \ldots\ldots [17]$$

and for narrow tubes it was reduced to

$$aV = g\frac{D}{4}\frac{h}{L} \quad \ldots\ldots [18]$$

Girard's coefficient a varied with the temperature and also with the diameter of the tube. It is noteworthy that his article contained a number of "viscosity" tables for various mixtures at different temperatures.

Following Girard, Navier (14), Poisson (15), and Stokes (17) have advanced very elaborate mathematical derivations showing that Girard's equation was correct for small, narrow tubes. Then Poiseuille's (16) experiments, published in 1842, virtually showed that the coefficient a in Girard's formula (Equation [18]) is proportional to diameter times fluidity. Poiseuille's equation read

$$V = kD^2\frac{h}{L} \quad \ldots\ldots [19]$$

Soon after, in 1854, Marcel Brillouin (18) showed by differentiation similar to Navier and Stokes, with a slight modification in the assumptions, that in small, narrow tubes the equation for velocity should be

$$V = \frac{1}{32}\frac{p}{L}\frac{D^2}{\mu} \quad \ldots\ldots [20]$$

and

$$p = 32\frac{\mu LV}{D^2} \quad \ldots\ldots [21]$$

This apparent theoretical contradiction in the derivations is cited for the purpose of demonstrating the fact that a theoretical equation is merely a filing case or container for an adopted set of assumptions. It is certain that the integral extensions of Navier, Poisson, and Stokes are mathematically correct the same as are those of Brillouin. The difference lies in the respective sets of assumptions. It will be found that the first three scientists following Girard assumed an additional resistance to the flow in proportion to the surface of contact, while the fourth one, following Poiseuille, did not include that resistance in his assumption. Navier expressed himself, and with great certainty, that the velocity in small tubes was independent of the thing called cohesion or viscosity. In his opinion the velocity depended almost entirely upon the adherence that exists between the fluid and the wall of the tube.

The Common Denominator

Coming back to Brillouin's equation, multiply both sides of Equation [20] by $V\gamma$; then

$$V^2\gamma = \frac{V\gamma}{32}\frac{pD^2}{L\mu} \quad \ldots\ldots [22]$$

$$V^2 = \frac{1}{16}\frac{D}{4L}\frac{VD\gamma}{\mu}\frac{2p}{\gamma} \quad \ldots\ldots [23]$$

$$V = \left[\frac{1}{4}\sqrt{\frac{D}{4L}}\sqrt{\frac{VD\gamma}{\mu}}\right]\sqrt{\frac{2p}{\gamma}} \quad \ldots\ldots [24]$$

In a similar manner, Equation [21] will read

$$p = 8\left(\frac{4L}{D}\right)\left(\frac{\mu}{VD\gamma}\right)V^2\gamma \quad \ldots\ldots [25]$$

There are, in the following, two sets of keynote equations placed in consecutive order to more clearly demonstrate their similarity. The common denominator or the meaning of the corresponding sets of assumptions is apparent.

First Set: Velocity Coefficient

$$V = [C]\sqrt{2\,p/\gamma} \quad \ldots\ldots [2]$$

$$V = \left[n\sqrt{\frac{D}{4L}}\right]\sqrt{2\,p/\gamma} \quad \ldots\ldots [7]$$

$$V = \left[1/\sqrt{f}\sqrt{\frac{D}{4L}}\right]\sqrt{2\,p/\gamma} \quad [11]$$

$$V = \left[\frac{1}{4}\sqrt{\frac{VD\gamma}{\mu}}\sqrt{\frac{D}{4L}}\right]\sqrt{2\,p/\gamma} \quad [24]$$

Second Set: Friction Coefficient

$$p = \left[\frac{1}{2C^2}\right]V^2\gamma \quad [3]$$

$$p = \left[\frac{1}{2n^2}\frac{4L}{D}\right]V^2\gamma \quad [8]$$

$$p = \left[\frac{1}{2}f\frac{4L}{D}\right]V^2\gamma \quad [12]$$

$$p = \left[8\frac{\mu}{VD\gamma}\frac{4L}{D}\right]V^2\gamma \quad [25]$$

A glance at the outline leads to the following analysis:

1 Equations [2] and [3] are universal, subject only to the law of falling bodies. All other influences are included in the coefficients.

2 Equations [7] and [8], the same as [11] and [12], are subject to the law of falling bodies and also to the resistance factor which is expressed in pipe diameters. This factor may be expressed as an orifice ratio, or any other restriction in the flowing stream. All other influences are included in the coefficient n when solving for velocity, or f when solving for pressure drop.

3 Equations [24] and [25] are subject to the law of falling bodies modified by the product $VD\gamma/\mu$ and to the resistance factor expressed in pipe diameters. This takes care of all cases below the critical velocity of the flow. The product $VD\gamma/\mu$ replaces the coefficients of the other cases.

4 The equations given can each be solved only for one unknown quantity, which is usually either V or p, or the coefficient of the given equation.

5 The shift from one equation to the other in no way affects the condition of the flow in the pipe. This seemingly very simple axiom is not generally understood.

6 Any given experimental solution for the coefficient in one of the equations invariably offers a solution for the corresponding coefficient in the other equation, when applied to the same conditions of flow.

Reynolds' Number

We are now coming to the most interesting question in our discussion. Since the hydraulic equations, as given in the previous chapter, were all available in various forms before the time of Osborne Reynolds, and since there are no additional equations of any consequence even now, one may ask: (1) What was Osborne Reynolds' discovery? and (2) What is the basis of the modern theory of fluid flow?

It is not difficult to answer the first question. The old Spaniards claimed that Columbus did not discover America. They said that Columbus was going west to reach India, and America being such a large continent, loomed up in his way and he couldn't pass it. The same is perhaps true of Reynolds' discovery. His experiments were made for the single purpose of determining the dividing line between viscous flow, following the law of Poiseuille, and turbulent flow subject to the less certain but available frictional resistance formulas. What actually happened is this: as long as the flow was viscous and laminar, the expression $VD\gamma/\mu$ was a definite entity or a single product. It did not matter how he varied each one separately, it was the product that determined the behavior of the flow according to the law of Poiseuille.

Reynolds then investigated what happened to the product after the critical point was reached. His actual statements, based on observations, were that the line of demarcation was not well defined, and that there was a certain period of unstable condition in which the flow might be either viscous or turbulent. After full turbulence was reached, Reynolds stated, neither the product nor any of the factors seemed to have any influence on the behavior of the flow.

It is more difficult to answer the second question, What is the basis of the modern theory of fluid flow? As the matter stood at the close of the last century, there were two independent formulas for the determination of frictional resistance in pipes. The engineers adopted the modification of the Chézy formula, while the physiologists, and later the chemists, took possession of the Poiseuille equation as derived by Brillouin.

It was known, however, that in the engineer's formula the coefficient f was not a constant. Darcy (19), in 1857, made f a function of the diameter. Weisbach and others made f a function of the square root of the velocity. Fanning (22) computed extensive tables giving numerical values for f varying with both diameter and velocity. Stanton and Pannell (24) were the first to plot experimental data to the parameter of the Reynolds number. This enabled them to represent the two modes of flow on one chart and to draw very useful conclusions.

Reynolds' experiments gave the hypothetical stage of the analysis. Stanton and Pannell's work justified the formation of the theory that hydraulic similarity should influence the coefficient of flow. Now the tendency is to establish this theory in the third stage; that is, to make it a law.

Briefly, the modern theory states that the analysis of dimensional equations makes it certain that the coefficient of friction and the coefficient of discharge for any flow through similar devices must be functions of the Reynolds number $VD\gamma/\mu$ as a single product and not otherwise.

Lord Rayleigh (23) showed the dimensional analysis and Dr. Buckingham (25) developed the π-theorem to prove this theory. In reality the π-theorem or the dimensional analysis is only another way of arriving at the mathematical relation between the respective sets of assumptions. After a study of the references cited I concluded, first, there is no proof, and second, no proof is necessary. If one believes the modern theory, he can believe it on the simple ground that the product is the determining factor in viscous flow, and therefore it should have some effect in the other regions. One may say by looking at the two sets of equations, as previously outlined: "Here it is, simply push a button on C and the Reynolds number comes out."

On the other hand, if one considers the complete analysis of the equations and the assumptions upon which they are based, and if he follows carefully the experiments that brought about this theory and especially those of Osborne Reynolds, he may agree with the author that the reason the product $VD\gamma/\mu$ comes out by pushing a button on C is because it does not belong there any more. The product has been disbanded, or at least may have been disbanded, and each one of the items may or may not have an influence on the behavior of the turbulent flow. The influence of one may or may not be the same as the influence of the other.

The main difficulty lies in the tendency to go so far as to make a law of this hypothesis or assumption. The outline of the equations has shown that there is no proof that the number retains its influence as a product in the case of turbulent flow because the relation is only one of mathematics and not of physics. The fact that Hodgson's (26) points for various fluids lie on the same curve does not prove this relation. The

fact that Stanton and Pannell's points do not all lie on the same curve does not disprove it. The points will fall nearly on the same curve for various fluids because the parameter contains (the) velocity times (the) density or the momentum of the moving particles, and the momentum of a moving particle has the same numerical value for the same differential pressure irrespective of the nature of that particle.

The Reynolds number is a very desirable parameter for recording experimental data on fluid flow. This parameter becomes a necessity when it is desired to plot on one chart part of viscous and part of turbulent flow, and also for the purpose of determining the region of demarcation between the two kinds of flow. It is imperative, however, to come to a complete understanding of the limitations to similarity that are subject to confusion by the application of this parameter.

Perhaps the thought can be expressed by drawing a comparison between "geometrical" similarity of construction and "hydraulic" similarity embodying the effect of geometrically similar construction. I asked Dr. Föttinger, the hydraulic engineer of the Technische Hochschule in Charlottenburg, how close experiments on geometrically similar models hold true on similar ships and airplanes, and he told me that the actual ship acts quite differently from the model. Thus the references made in this respect to hydraulic similarity as applied to construction of models are obviously misleading. The ship or the airplane is expected to perform in a "similar" manner to the model, but the performance is not expected to be exactly the same. That is, the experimental coefficient may or may not be the same in both cases. If it is within a few per cent, the model served the purpose well. In the case of flow measurement, the 1-in. pipe may be considered the model and the 10-in. pipe the final product. The action of both may be similar, but they may or may not be identical. The "experimental coefficient" may be different.

My objection, therefore, is not against the theory itself but against the method of its application. There is an abundance of theory on the subject, but there is a woeful lack of reliable experimental data. If this new theory will be confined to the use of the function as a parameter, made subject to experimental data, there will be no harm done. If, as the tendency grows now, the theory is set in the ranks of a law and its advocates will insist that experiments made on a "model" pipe can be safely applied to all other sizes in the region of turbulent flow, there will be a good deal of harm done because it will reduce the amount of experimental data that would have been otherwise accumulated.

The present argument on similarity may be compared with the case of M. Couplet, the first experimenter on pipe friction, and whose work was published in 1732. M. Couplet was surprised to find that the rule of Mariotte for the flow of water through short nozzles did not apply to the long pipes of the water works at Versailles. It is perhaps just as inadequate to expect that the laws of similarity, based on definite simplified assumptions of perfectly similar conditions, should apply directly to a measuring device in ordinary commercial pipe. Then there is no argument, and we agree that similarity is not fulfilled in the ordinary installations for fluid measurement.

On the other hand, considering the position of Couplet at that time, would he be expected, when additions were to be made to the water works of Versailles, to assign a diameter to the main such as would be derived from Mariotte's law or to order one that his experiments would indicate was adequate for the proper supply? The same should be true to a certain extent with the case at hand. If one finds that the experimental coefficient of the measuring device, constructed according to the present practice of measurement, shows a different value for different sizes of pipes, should he be advised to use the same coefficient for all sizes of pipes on the ground that, if all the installations in the various pipes were perfectly similar, they would all result in the same coefficient?

Here is the difference. The laws of similarity, or the statement that the flow in the pipe *must* be the same for the same value of the Reynolds number, may be physically correct, the same as the law of falling bodies or the relation between pressure and velocity. But in this latter relation when the results of a given test deviate from the law, we say that "there is the experimental coefficient," and we use that coefficient for practical application of the given law. In the case of similarity, as the argument would have it, if we find that the results of a given experiment deviate from the theoretical expectations, we are expected to say that "the reason is that the installation was not strictly similar."

Effect of Pipe Diameter

In 1922 the author (25*b*) presented to the Society the results of experiments on the flow of air through orifice plates in various sizes of pipes. These results showed that the coefficient of discharge of the orifice plate increases for the same orifice ratio as the diameter of the pipe decreases, irrespective of any other changes in the condition of flow. As an explanation of this phenomenon he stated in Par. 92 of the paper that—

The jet issuing from the orifice does not contract to the same extent in the smaller sizes of pipes. This is probably due to the fact that the portion of the flow which is restricted by the orifice has a proportionally lower velocity due to the increased skin friction in smaller sizes of pipes.

Mr. Hodgson, in discussing that paper, stated that "all the tests could have been carried out on one diameter of pipe had the $VD\gamma/\mu$ relation been used. . . . Had the orifices been similar, or had the edges been beveled off on the downstream side so that the ratio of thickness of the edge to diameter of pipe was kept constant, only one set of tests would have been necessary to determine the coefficients of discharge for orifices of any area ratio for any diameter of pipe."

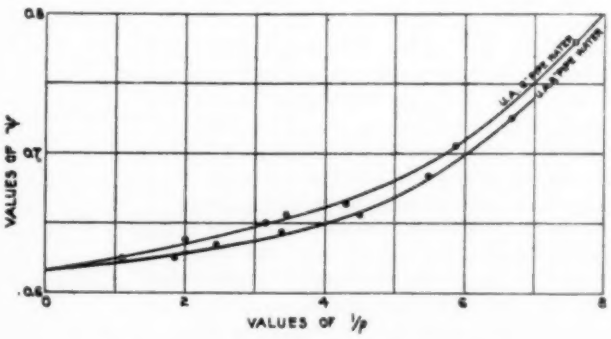

Fig. 1 Flow of Water Through Pipes
(Gaskell, Figs. 5 and 6.)

This criticism led the author to investigate the validity of the statement. From the recorded literature and from his own observations it appeared that the orifice-plate thickness up to $^1/_8$ in. would have no effect on the flow when the spacing was measured from the front face of the plate.

It so happened that, having used for the tests a blower of a given capacity, it was possible to obtain about four times higher velocities in the 3-in. pipe than in the 12-in. with the same ratio orifice. The kinematic viscosity was the same in all the tests. Then, if the supposition were correct, we should have found the same coefficient for the 12-in. pipe at the corre-

spondingly reduced speed as for the 3-in. pipe at the higher speed. Moreover, the increase in velocity in any of the pipes did not seem to change the coefficient; then the same should be

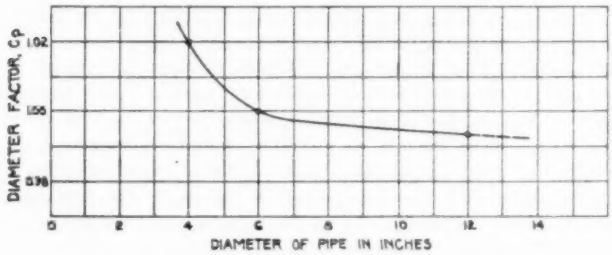

FIG. 2 FLOW OF WATER THROUGH PIPES
(Davis & Jordan, Fig. 10.)

true for the change in diameter. The actual tests, however, have shown the coefficient of the 12-in. pipe to be from 3 to 5 per cent lower than the coefficient of the 3-in. pipe for the corresponding orifice ratios.

The early experimenters have limited their tests to thin-plate orifices discharging from large containers. In such cases the effect of velocity distribution is practically unchangeable. There is, however, a good deal of data by recent experimenters which demonstrate beyond doubt that the orifice coefficient varies for different sizes of pipes at the same numerical value of the Reynolds number. Whatever the reason is for this phenomenon, the fact remains the same and should be complied with in practical measurement.

1 Holbrook Gaskell (23*a*), experimenting on the flow of water through a 6-in. and an 8-in. pipe, showed that the 6-in. pipe had higher coefficients than the 8-in. pipe for the same diameter ratio of the orifice. Fig. 1 is a reproduction of Figs. 5 and 6 in his paper. Mr. Gaskell employed orifice plates designed by John L. Hodgson for his tests.

2 Davis and Jordan (25*a*) have gone a step farther. They have demonstrated the variation of the orifice discharge coefficient with the pipe diameter in their tests on 4-in., 6-in., and 8-in. pipes, and have prepared a curve (Fig. 10) giving the "Diameter Factor" derived. (See Fig. 2.)

3 J. M. Spitzglass (25*b*) in the experiments referred to has shown the variation of the orifice coefficient with the size of pipe for diameters from 3 in. to 12 in. The curves showing that variation are reproduced in Fig. 3.

4 The Verein Deutscher Ingenieure (26*b*), in their publication "Regeln für Leistungsversuche, etc.," show on page 16 a table of orifice coefficients varying with pipe sizes from 100 mm. to 600 mm., based on the results of experiments by Jakob and Kretschmer. A corresponding set of curves, on page 49 of the same pamphlet, show the systematic variation of the coefficient with size of diameter, and also the relative change of the coefficient with the variation of pipe size for given orifice ratios. This curve is reproduced in Fig. 4.

5 Dr. Walter Pflaum (27) experimented on three sizes of pipes, 50-mm., 80-mm., and 100-mm. His Fig. 24 shows the variation of the coefficient with the pipe size. In his case, the sizes being very small and the taps close to the orifice section, each pipe shows a different shape of curve. The difference is very pronounced between the 50-mm. and the 80-mm. pipe. The curve is reproduced in Fig. 5.

6 Dr. R. Witte (28) experimented on the flow of oil, water, air, and steam in sizes of pipes from 50 mm. to 500 mm. On page 6 of his paper, Fig. 21 shows five distinctive curves plotted for five pipe sizes, 50 mm. to 500 mm. The curve is reproduced in Fig. 6. A paragraph in italics on the same page points out the fact that while in the case of his round nozzles the effect of diameter variation was not noticeable, the sharp-edged orifice showed a definite decrease in the value of the coefficient with the increase of the pipe diameter.

7 Jakob and Kretschmer (30) have gone into this subject to a larger extent than any of the other experimenters. They have tested orifices of various ratios in sizes of pipes varying from 125 mm. to 1000 mm., and the pipes were not all of the same absolute wall roughness. Fig. 7 is a reproduction in part of Fig. 72 of their bulletin, showing the variation of the coefficient for the given constant value of the Reynolds number. Other sets are

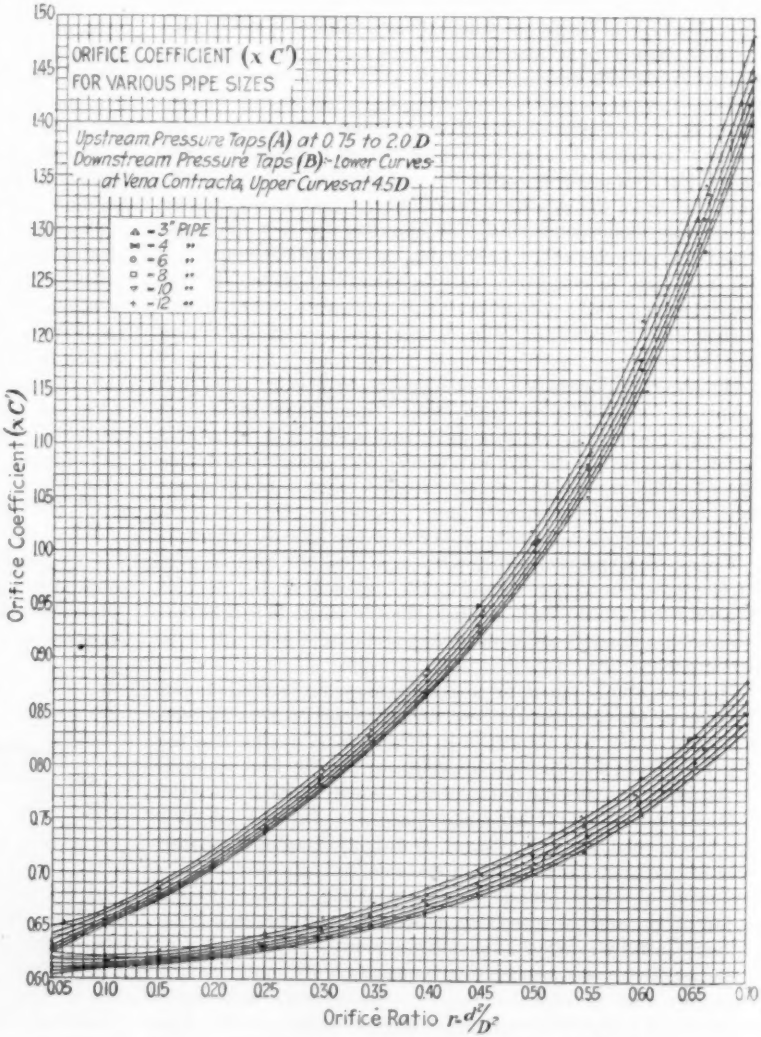

FIG. 3 ORIFICE COEFFICIENTS FOR VARIOUS PIPE SIZES

shown of the same form for different constant values of the Reynolds number.

A very interesting discussion is given by these authors on pages 20 to 27, under the heading "Effect of Pipe Diameter on the

Value of the Orifice Coefficient." The authors give two reasons for the variation, one depending upon the relative smoothness of the pipe, and the other upon the ratio of the velocity in the pipe to the velocity of sound.

The first effect is demonstrated in Fig. 8, which is a reproduction of Fig. 73 in their bulletin. The reasoning of the authors is that when two pipes, one large and the other small, are of the same absolute wall roughness, the relative roughness will be smaller in the larger pipe. The result will be that the larger pipe will have a flatter curve of velocity distribution than the smaller one. Accordingly a larger portion of the fluid will be retained by the orifice wall and diverted toward the center, thus resulting in a larger contraction for the same orifice ratio. The authors show by differentiation that the orifice in the smaller pipe will pass more fluid per unit of area for the same differential pressure than the orifice in the larger pipe.

The second reason given by the authors has reference to the work of Odquist (26*a*), in which it was shown that even in the case of smooth pipes, or such that have the same relative smoothness, there would still be a variation of the coefficient with the variation of the absolute size of pipe. The authors think that their tests have shown that the main cause of the variation is the relative roughness of the pipe; still the equations derived by Odquist show that the coefficient is a function also of the

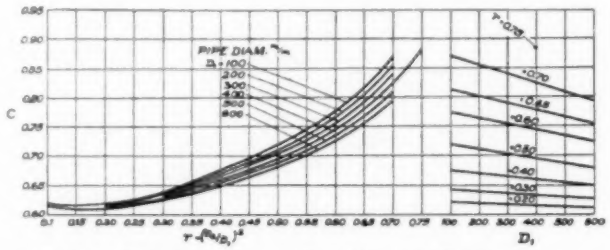

FIG. 4 *C* AS A FUNCTION OF PIPE SIZE AND ORIFICE RATIO
(Jakob & Kretschmer, V.D.I. Bulletin, Fig. 54. *C* is defined from $Q = 0.25\,\pi\,C_3^2 D\sqrt{2gh}$.)

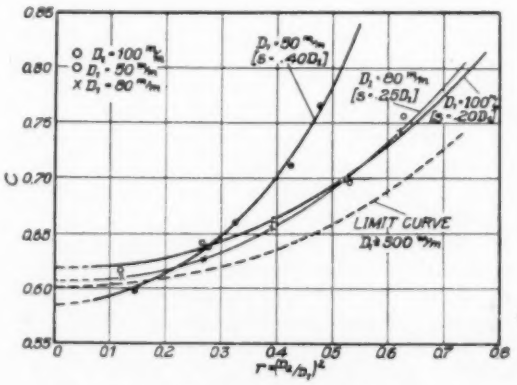

FIG. 5 FLOW OF WATER IN PIPES
(Pflaum, Fig. 24.)

absolute diameter of the pipe, as well as of the two dimensionless ratios, the Reynolds number and the acoustic velocity of the flow. All agree that the extent of this function can be determined only by experiment. There is, however, a further aspect to be considered.

It is by no means established that in the case of turbulent flow two pipes of the same relative roughness and different in size will have the same symmetrical curve of velocity distribution. Here again the basis of the mathematics is all a matter of assumption. One assumes that the retardation at the wall is transmitted through the medium of the fluid in a symmetrical way from the wall to the center. This is equivalent to assuming a symmetrical curve of velocity distribution for all sizes. If, however, one realizes that in the case of turbulent flow the effect of the wall, or what is termed skin friction, penetrates only a certain linear distance from the wall in each case, then even in pipes of the same relative roughness the velocity distribution

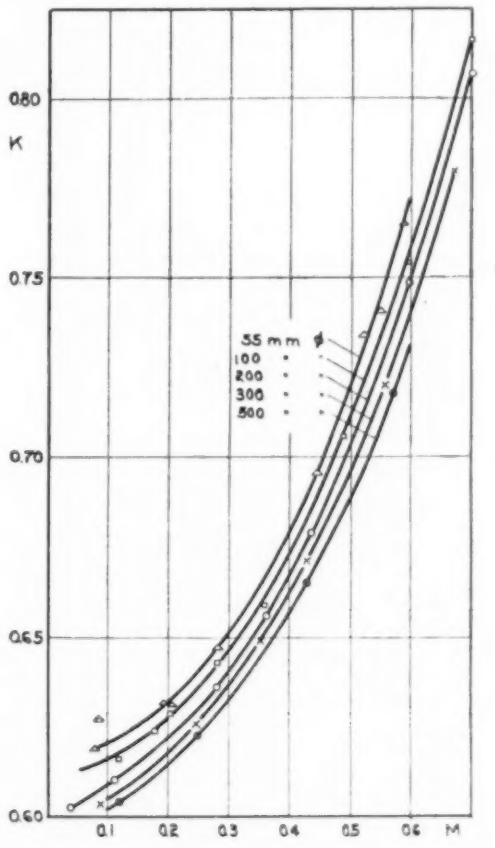

FIG. 6 FLOW OF VARIOUS FLUIDS IN PIPES
(Witte, Fig. 21.)

should be flatter in the larger pipe than in the smaller. Hence the reason for the variation of the coefficient with the absolute size of the pipe. How much this variation is, can be determined only by experiment.

THE REGION OF INSTABILITY

There is another tendency traceable to this theory which will be harmful to future developments. Hydraulic similarity is given the right of way in our recent publications of experimental work. However, it is used mainly for the establishment of the theory, and little attempt is made to follow hydraulic similarity in actual practice. A striking example of this nature is the lack of care used in the placing of pressure taps on the low-pressure side of an orifice plate. It is not appreciated that the jet issuing through the orifice has parallel lines of flow only at the *vena contracta*. Still even in experimental work connections are often made only at points where the flow is not parallel, where turbulence begins and no similarity of action should be expected.

As stated, Osborne Reynolds (20) made his experiments for the purpose of determining the dividing line between the two types of motion, streamline flow on one side and turbulent flow on the other. However, Reynolds' discovery showed that it was

not a line but an area or a region of instability between the two types, in which the flow changed from one condition to the other at the slightest disturbance in the stream.

Lord Rayleigh (23), immediately following Reynolds' work, set out to find a theory "to explain the complete change in the laws of flow which supervenes when the tubes are of larger diameter and the velocities not very small." While introducing the

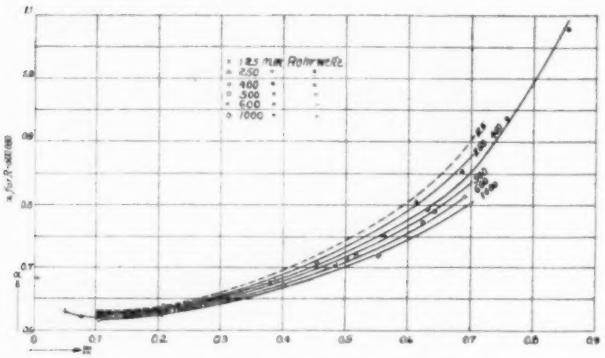

FIG. 7 FLOW OF WATER IN PIPES
(Jakob & Kretschmer, Fig. 72.)

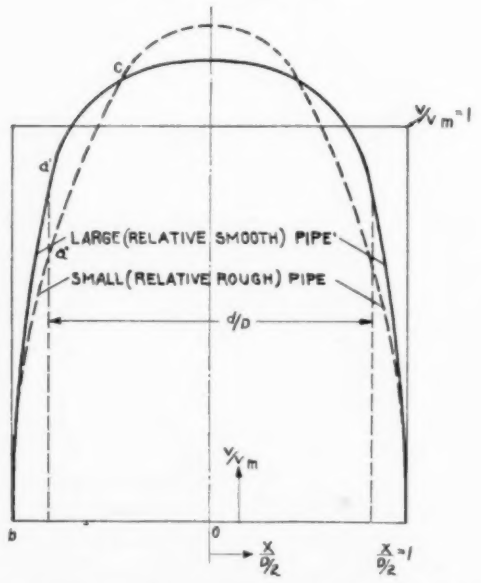

FIG. 8 EFFECT OF PIPE DIAMETER ON VALUE OF ORIFICE COEFFICIENT
(Jakob & Kretschmer, Fig. 73.)

subjects Rayleigh refers to Sir G. Stokes' theory of viscous flow and to Reynolds' application of the theory of dynamical similarity and to the experiments which showed "that the change in the law of resistance occurs when $VD\gamma/\mu$ has a certain value." To this Rayleigh adds: "The conclusion is perhaps most easily reached by applying the method of dimensions to the expression," etc. The application as given by Rayleigh shows clearly that the dimensional theory is only a method by which the physical balance of any equation is proved to comply with the corresponding set of assumptions. In the following derivations the parts "quoted" are copied from Rayleigh's text.

Let $P = p/L$, the ratio of the pressure drop to the length of the tube. "The dimensions of this ratio are those of a force divided by a volume. If it is assumed that this ratio may be expressed in terms of ν (equal to μ/γ, D, γ, and V in the form"

$$D^x \nu^y \gamma^z V^n$$

The dimensions of the quantities are:

$$P = ML^{-2}T^{-2}$$
$$D = L$$
$$\nu = L^2T^{-1}$$
$$\gamma = ML^{-3}$$
$$V = LT^{-1}$$

Therefore

$$ML^{-2}T^{-2} = L^x(L^2T^{-1})^y (ML^{-3})^z (LT^{-1})^n \quad \ldots\ldots (26)$$

Removing parentheses gives

$$ML^{-2}T^{-2} = M^zL^{x+2y-3z+n}T^{-y-n} \quad \ldots\ldots (27)$$

Equate the exponents; then, from M, $1 = z$; from L, $-2 = x + 2y - 3z + n$; from T, $-2 = -y - n$

Hence $x = n - 3, y = 2 - n, z = 1 \quad \ldots\ldots [28]$

and $P \sim D^{-3}\nu^2\gamma(DV/\nu)^n \quad \ldots\ldots [29]$

"Since n is here indeterminate, all that can be inferred from dynamical similarity is that

$$P = D^{-3}\nu^2\gamma f(DV/\nu) \quad \ldots\ldots [30]$$

where f is an arbitrary function."

"For capillary tubes and moderate velocities P varies as the first power of V, so that in Equation [29] $n = 1$. In this case

$$P = kD^{-2}\nu\gamma V \quad \ldots\ldots [31]$$

k being an arbitrary constant. When, on the other hand, DV/ν is great, experiment shows that $n = 2$ nearly. If this law be exact, Equation [29] gives

$$P = k'D^{-1}V^2\gamma \quad \ldots\ldots [32]$$

independent of ν. The second power of the velocity and independence of viscosity are thus inseparably connected."

It is well to note that while Rayleigh refers to Stokes' theory of viscous flow his solution of dimensions gives Poiseuille's equation and not Girard's formula as derived by Stokes. This emphasizes the importance of checking the physical balance of an equation. Equation [31] is identical in form with Equation [21], which is dimensionally correct. Equation [18] (Girard's formula) is dimensionally wrong, having an extra length in the second term, and the coefficient a must be considered as a physical constant. Equation [32] is identical in form with Equation (12), which is dimensionally correct.

After showing the method of dimensions, Rayleigh turns his attention to the formation of eddies with the reduction of viscosity. "From the description and drawings given by Reynolds it is natural to suppose that in the absence of viscosity the stratified motion would be unstable . . ." Rayleigh experimented for that purpose and found that stratified or linear flow is just as stable in the absence of viscosity. (The stream from a nozzle is a good example.) Rayleigh further makes the following significant statement with reference to the region of instability in a stratified or linear flow:

> We are thus confronted with a difficulty. For if the investigation in question can be applied to a fluid of infinitely small viscosity, how are we to explain the observed instability which occurs with moderate viscosities? It seems very unlikely that the first effect of increasing viscosity should be to introduce an instability not previously existent, while, as observations show, a large viscosity makes for stability.

This citation of physical phenomena is to my mind the keynote of the situation. The dimensional analysis shown by Rayleigh

and the π theorem developed by Dr. Buckingham do not apply to physical phenomena outside the given specified assumptions.

The Stanton and Pannell curve on fluid friction which was published 24 years later is an illustration of similar phenomena showing the area of instability between two types of motion. A reproduction of this curve is shown in Fig. 9. In that figure

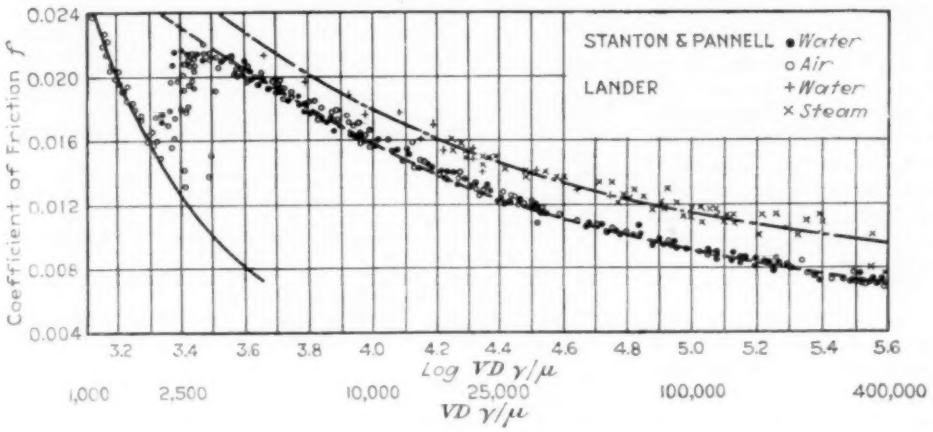

FIG. 9 COEFFICIENT OF FRICTION f AS A FUNCTION OF $VD\gamma/\mu$
(From Grunwald and Engel, Z.V.D.I., May, 1928.)

the friction coefficient, in the Chézy formula, is plotted against the log of the Reynolds number. Note at the left the stable condition of the viscous flow, and at the right the equally stable extension of the turbulent flow. Lord Rayleigh would probably say again, Why should the first effect of increasing the Reynolds number introduce an instability, while a further increase restores the stability? And further, why should this instability escape notice in the theoretical equations which cover the behavior of the fluid throughout the entire range?

With this idea in mind the author looked for a similar exposition of instability in the flow through a restricted opening. He realized that it was not the turbulent flow that was unstable, but it was the change from streamline to turbulent flow that produced the instability. One could comprehend why the results of measurement become uncertain when the low-pressure orifice tap was moved from the *vena contracta*, because the pressure came from a section where the flow was changing from streamline to turbulence and the pressure conditions were unstable. This

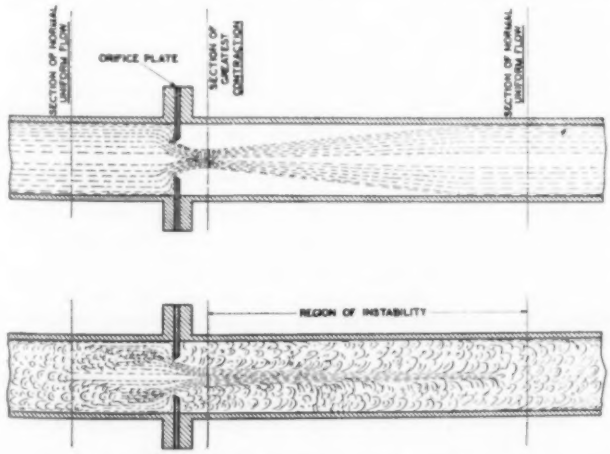

FIG. 10 REGION OF INSTABILITY IN FLOW SECTION
(Above, incorrect presentation of flow condition; Below, correct presentation of flow condition.)

phenomena is shown diagrammatically in Fig. 10. The upper section shows the customary presentation of the orifice or venturi section, which on the face of it is incorrect. The lower section shows the changes that are probably taking place in the section. The turbulence is changed into stratified or linear motion at the approach to the orifice, reaching full stratification at the *vena contracta*. Beyond this point the lines break into eddies, reaching the condition of turbulence again at several diameters below the section of the orifice. In Osborne Reynolds' language, the upper section shows the way an army marches on a parade; the similarity is perfect. The lower section shows the way an army marches in action, under the fire of the enemy.

SURVEY OF RECENT PUBLICATIONS

Six articles of special merit have appeared in the recent literature on the subject of fluid flow. Three of them were published in Germany, one in England, and two in the United States. Each gives full consideration to the laws of similarity.

The German authors, Messrs. Pflaum (27), Witte (28), and Jakob and Kretschmer (30), have used the Reynolds' function as a parameter with the understanding that there are other influences that may affect the coefficient. That is, they have shown that while it is advantageous to plot the coefficient on the parameter of similarity, the coefficient does not necessarily have to be on the same curve in all cases. They have shown that the coefficient of an orifice plate varies with the size of the pipe when plotted to the scale of the Reynolds' function. In other words, they have considered similarity as a theory and not as a law. A theory needs an experimental coefficient, and their experiments have shown that the coefficient, in its practical application, varies with the size of the pipe.

Mr. Hodgson (29), of England, stressed the validity of the viscous-flow criterion to a larger extent. In fact the title of his paper is "The Laws of Similarity." Mr. Hodgson believes that a coefficient obtained on a small size of pipe will be duplicated on a larger size if both the hydraulic and geometric similarity are maintained. He points out, however, that: "If in practice the pipes vary in roughness, the coefficients of discharge for otherwise geometrically similar orifices will not be the same, especially for the smaller pipes where a given change in the roughness produces the greatest effect."

Messrs. Bean, Buckingham, and Murphy (31), of the Bureau of Standards, have tested three sizes of pipe with a large number of orifice plates. They have combined the results of the 6-in. and 8-in. pipes into an empirical equation for the orifice coefficients. They have rejected the data for the 4-in. pipe because it showed consistently higher values for the coefficient than the other two pipes. They have gone extensively into the theory to show that the "absolute" size of the pipe could not have any effect on the coefficient. In other words, they believe that geometrically similar shapes must produce the same hydraulic similarity irrespective of size. They have arrived at this conclusion with the understanding that it applies to perfect similarity, which, as they have demonstrated themselves, is seldom obtained in practice.

Mr. Smith (32), in his contribution, has gone a step farther.

He has brought the modern theory of fluid flow or the laws of similarity to the front in a very forcible and convincing manner. His work is very valuable as a guide for determining the coefficient of discharge in and near the region of viscous flow. His contention is that the coefficient is still a function of the Reynolds number in turbulent flow, where according to his indications, the function becomes a constant and the curve remains "flat" for all values of the criterion. This means that after a certain turbulence is reached, the coefficient is independent of the charge or variation of either one or all of the factors of the criterion. However, this is not borne out in practice, since the coefficient does not have the same value for the various pipe sizes although it appears to be independent of the variations in the other quantities of the Reynolds number—velocity, viscosity, and density. This difference of the coefficient with size is due first to the practical difficulty of obtaining exact geometrical similarity with the various sizes of pipe and second to the effect of the boundary layer which may vary with the absolute size of the pipe.

Conclusion

Looking back on the historical development of fluid-flow measurement, one is greatly impressed with the effort exhibited first in one and then in the other branch of this development. It started from Torricelli's discovery, in 1643, of the velocity of the water jet. The main study then was the flow of water through orifices and jets issuing from large tanks. In the course of a century the attention of scientists was turned toward the investigation of friction drop of pressure in pipes. Almost all the theories on fluid flow of the succeeding two centuries have as their object the motion of fluids in tubes, pipes, and channels.

The practical application of fluid-flow measurement is nearly all a product of the twentieth century. In the two preceding centuries the profession was interested mainly in how to convey and deliver fluids through given conduits. The chief interest at present is how to measure the fluid with a reasonable degree of accuracy.

In both cases the development of the subject was greatly advanced by the analytical work of the various scientists in their respective times. In all cases it was experimental discoveries that formed the basis of scientific analysis.

It is hoped that this brief résumé of the development of the art will bring about a better understanding of the effects of hydraulic similarity as related to the geometrical similarity of the various devices. Geometrical similarity is of great importance, and devices which are geometrically similar will make the operation more uniform. Geometrical similarity is a matter of construction. Hydraulic similarity is a matter of experiment. Large sizes may or may not show the same results as the smaller ones.

Notation

A = area of conduit
a = first constant in Girard's formula
B = wetted perimeter
b = second constant in Girard's formula
C = coefficient of Torricelli's equation
D = pipe or tube diameter
f = coefficient of friction
g = acceleration of gravity
h = differential head
k = constant in Poiseuille's formula
L = length of pipe
n = constant in Chézy's formula
p = differential pressure
$r = A/B$ = mean hydraulic radius
$s = h/L$ = hydraulic slope
V = mean velocity
γ = density
μ = viscosity
ν = kinematic viscosity.

Discussion of Papers on Fluid Flow[1]

LOUIS GESS.[2] In the opening paragraph of the paper by Messrs. Beitler and Bucher the authors make a statement regarding the accuracy demanded by the user of fluid meters today. It would have been well, the writer believes, to have made a statement that in order to obtain these accuracies the customer must pay more attention to the recommendations of the Fluid Meter Committee and other authorities. The results obtained by these tests would never have been possible if the investigators had not taken all the precautions which they did.

No mention is made by the authors as to the leakage tests on the condenser used when making the tests with steam.

G. D. CONLEE.[3] The paper by Messrs. Beitler and Bucher is a real addition to the volume of data on orifice coefficients. It is really surprising how few reliable data of this sort are being published. It is the writer's hope that the promise made will be fulfilled and that these data will be very much extended.

The advocates of similarity tell us that data obtained on one size may be applied to all other sizes of similar construction. This may be theoretically correct, but by all means give us actual test data on reasonable-sized commercial pipes on which to base the extension of values into the territory where actual experiments are out of the question.

A point of great interest in orifice design, or rather installation, is the location of the downstream, or low-pressure, tap. Practical experience has shown that this tap must be located at the *vena contracta*, or point of minimum pressure, and if the tap is not so located the results cannot be exactly predicted.

The accompanying Fig. 1 is a plot showing the location of the *vena contracta* with reference to pipe diameter and orifice ratio. The curved line was obtained from the tests made by Mr. Spitzglass and reported on in his "Orifice Coefficients." The straighter line is a location defined as 2.5 times the height of the orifice rim, that is, 1.25 $(D - d)$, where D is the pipe diameter and d the orifice diameter. The small circles show the various points obtained from this paper.

It is to be noted that the two are very close together, the difference being less than the possible effect of the pressure connections used. They were of $^3/_4$-in. brass pipe which probably had an internal diameter of about $^1/_2$ in. which corresponds to nearly 0.1 on the scale of abscissas.

From these curves it is obvious that the greater the orifice ratio, the nearer to the orifice is the *vena contracta*. One thing not shown in the plot, but generally accepted, is that the higher the orifice ratio, the more critical the tap location becomes. As a consequence, if it were possible to keep all orifice ratios below, say, 60 per cent, there would be very little trouble due to improper tap location. This is a practice adhered to in the measurement of natural gas. It is for this reason that the Bureau of Standards' tests in paper No. 49 were not satisfactory for higher-value orifice ratios. (See p. 589.)

In the use of flow meters for the measurement of steam and water, due to the high velocities experienced, it is necessary to use high ratio orifices, and the writer believes that carelessness in locating the low-pressure tap has had a great deal to do with errors in metering and results which were not comparative.

The data on compressibility are very interesting and give some direct information on this subject. With the very high steam velocities used, up to 20,000 ft. per min. in some cases, the orifice ratios and differentials are both high and the effect of compressibility has caused the writer a lot of thought.

In the second edition of "Fluid Meters," page 58, is a table of "Values of Factor Y" based on condition p_1. Y is the theoretical factor to be used for correcting the hydraulic equation for the effect of compressibility. These values are carried out to $R = 2.0$, or $d/D = 0.50$, a value for orifice ratio which is of little use in present-day steam measurement.

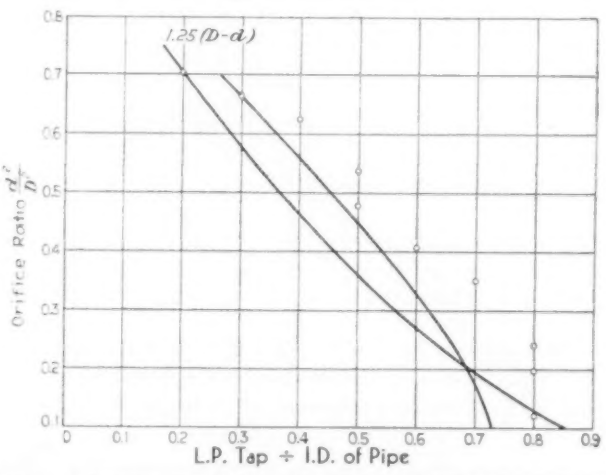

FIG. 1 LOCATION OF "VENA CONTRACTA" WITH REFERENCE TO PIPE DIAMETER AND ORIFICE RATIO

These values have been extended to cover higher ratios and greater pressure drops. We have not had the opportunity of making sufficient tests to verify the extent of this correction. However, in a number of cases we have been able to check the output steam from boilers against an input water meter. Without the application of the compressibility correction, the steam meter reads higher than the water meter. When this *theoretical* correction is made for compressibility, there has been in every case a reasonable spread between the water and the steam. Fortunately it has been possible to develop a device which would automatically correct for this condition, and we have had this device in use for the last year.

R. E. SPRENKLE.[4] Throughout the series of tests by Messrs. Beitler and Bucher on the six-inch-size pipe, using orifice and nozzles as the differential-pressure-producing media, the authors of this paper used exceptionally great care in watching all the fine points pertaining to this calibration work in an effort to eliminate as many unknown factors as possible. Attention is called to the method of reading static pressures on the inlet side of the orifice, by means of a calibrated mercury manometer instead of the usual pressure gage. All readings of this U-tube were corrected for all changes in barometer, temperature, relative

[4] Mechanical Engineer, Bailey Meter Co., Cleveland, Ohio. Assoc-Mem. A.S.M.E.

humidity, etc. An earnest endeavor also was made to hold the steam conditions absolutely constant for the duration of the run. This included a long warming-up period in order to be sure every condition was stabilized absolutely so as to prevent any energy losses due to any change in the steam conditions.

Mention was made in the appendix to this paper, of the correction applied to the two sides of the water manometer for the unbalanced air column. This is a refinement which, to our knowledge, has not been duplicated in any previous work. An idea of the magnitude of this correction is gained from Fig. 2, which shows the relation between the unbalanced air column on one leg of the U-tube and the necessary correction to be applied to the manometer readings to correct for this unbalanced head. It will be noted that at air pressures of 75 lb. abs. a correction of approximately 0.3 per cent is necessary, which is an appreciable amount in this type of calibration work.

The radiator and reservoir connections to the steam pipe, as shown in Fig. 14 of the paper, were so designed as to maintain equal water columns on the reading manometer. This pre-

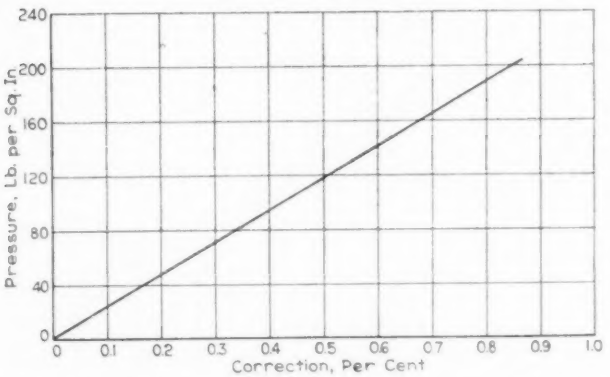

FIG. 2 CURVE SHOWING CORRECTION FOR PRESSURE OF AIR ABOVE WATER COLUMN

supposes an equal water level in both connections, this water level starting with the offset gate valve. While there is no reason to suspect that equal water legs did not exist in this series of tests, yet since it was not possible to see, visually, these water levels in the gate valves, some doubt was expressed as to whether this was the best type of apparatus to use in accurate laboratory calibration methods. The scheme of steam-flow calibration hook-up, as shown here in Fig. 3, was then devised and has now been in operation for some time. This scheme does away with the radiator connection as shown in Fig. 14 of the paper, and in its place is substituted essentially a simple water manometer connected through condensate chambers directly to the steam line.

Provision for cooling these manometer connections is made by introducing at the top of each manometer leg high-pressure air at regular intervals. Before readings are taken on the water manometer, the air is admitted to the manometer system by closing valves 1, opening valves 2, and opening the high-pressure-air valve supply. The rate of admission of air to each leg of the U-tube column is regulated by the needle valves 4. By this method the connecting piping between the manometer and the steam line is blown out thoroughly, thus cooling the tubes. Excess condensation is drained out of the condensate chambers whenever necessary, but experience with this device has shown it is not necessary to remove the condensate very often.

Corrections are also made in this system for the unbalanced air column on top of the manometer, as well as for the temperatures in the manometer itself.

SANFORD A. MOSS.[6] A great deal of matter in the three papers is concerned with attempts to measure fluid flow with accuracy with use of orifices in thin plates. There are cited as difficulties

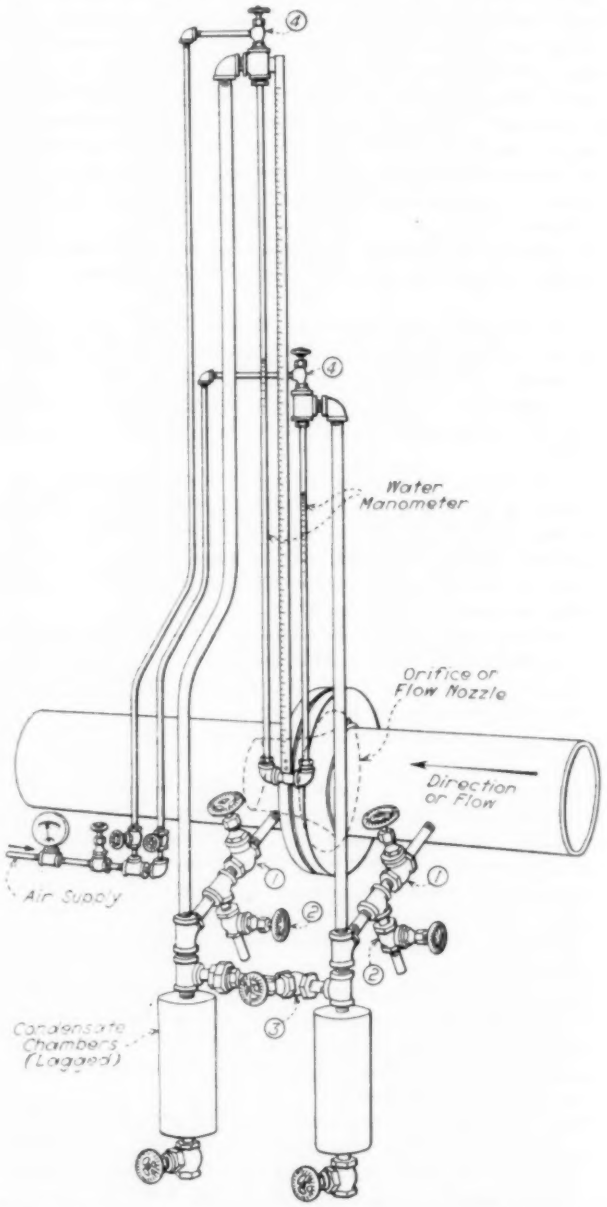

FIG. 3 METHOD OF MEASURING DIFFERENTIALS AS PRODUCED BY STEAM FLOW AT OHIO STATE UNIVERSITY

in this connection, the failure of the *vena contracta* to follow the dimensional laws, the difficulty of location of the downstream pressure taps, the failure of the coefficient with steam as found by Messrs. Beitler and Bucher to follow the theoretical expansibility laws, the disagreement of the coefficients of these gentlemen with those of Judd and Spitzglass, and the raggedness of their plotted observations in spite of their obvious care in making the experiments.

Of course a conclusion which can be drawn is that when accurate flow measurement is wanted, one should not use an

[6] Mechanical Engineer, Thomson Research Laboratory, General Electric Co., Lynn, Mass. Mem. A.S.M.E.

orifice in a thin plate at all, but should use a venturi meter, or nozzle with well-rounded approach. This is illustrated in the paper of Messrs. Beitler and Bucher, although it is preferable to use a smaller nozzle diameter in proportion to the pipe size. Such nozzles have been presented in a number of A.S.M.E. papers and were used as primary standards for calibration of orifices in thin plates in the Bureau of Standards paper by Bean, Buckingham, and Murphy cited. With such nozzles all questions of dimensional similarity are concerned only with the very small differences between 0.96 and 1.00.

It is to be noted that the complicated factors involving the ratio of pipe to nozzle diameter can be avoided by use of an impact tube instead of a static hole for the initial pressure. This may be before or after the nozzle.

The factor Y and the acoustic ratio x/n as used in the papers are very convenient ways for presenting results for all kinds of fluids in a single formula. However, if one deals with compressible fluids only, there is a slight extra complication in finding the results for an incompressible fluid, and then multiplying by a factor Y which is a function of x/n. It is somewhat simpler in dealing with gas only, to use a single formula, expressly arranged for the compressibility of the problems at hand.

Louis Gess.[6] Referring to Chapter I of Mr. Smith's paper, which is offered as a basis for the revision of Part I of the A.S.M.E. Fluid Meter Report, undoubtedly a revision of that report is necessary. Since it is desired that it be widely read by the users of fluid meters, the revision should be carefully done. A large number of these readers will be only interested in the subject generally, and not in theoretical discussions. The writer would suggest, then, that the first portion be written primarily for the engineer who wishes to know something about the subject, and has only a limited amount of time in which to do so, and that the second portion be added for the benefit of those who wish to know something of the theory of fluid meters. If the report is handled in this manner it will be equally satisfactory to both classes of readers.

R. E. Sprenkle.[7] The writer has enjoyed very much studying Mr. Smith's paper and its application to commercial metering, and believes that the data it presents will prove of great value to the art of metering.

Smith's Fig. 2 showing the relation between the expansion factor Y and the acoustic ratio x/n is very interesting and represents a decided advance over the information as published in the second edition of Part I of the A.S.M.E. Fluid Meters Report. This curve is especially interesting in view of the research work on steam measurement as being carried on by the Ohio State University at the present time on three- and six-inch steam lines. In this research all orifices used have throat connections, that is, the inlet connection is made one diameter on the inlet side of the orifice and the outlet connection at the *vena contracta*. Results of this study of the adiabatic expansion of the gaseous flow through a 50 per cent ratio concentric orifice are shown on the writer's Fig. 4. By plotting these data against the acoustic ratio as was done in Mr. Smith's Fig. 2, it is indeed gratifying to note that the curve expressing this relationship coincides almost exactly with the 40 per cent ratio orifice curve as shown in Mr. Smith's Fig. 2. Mr. Smith's curve shows a slight curvature, whereas the data which are shown on the writer's Fig. 4 plotted up to be substantially a straight line. However, the difference is so slight that it can be disregarded for all practical purposes. It is presumed from the data given on the figure that air was used as the flowing medium, since the value of n, or the ratio of the specific heats of the gas for all the solid lines, is given as 1.408, which is that of air.

Under the caption entitled "Standard Differential Producers" definitions are given for venturi tubes, venturi nozzles, venturi nozzle tubes, flow nozzles, and orifices with flange, throat, and pipe-line connections. This group should be enlarged to include other primary devices, such as various forms of pitot tubes, eccentric and segmental orifices, orifice segments, and venturi segments. Better yet, it would be advisable, in the writer's opinion, to omit this classification from this proposed revision of the A.S.M.E. Report, for descriptions of all the standard types of differential pressure-producing devices are covered in detail in Part 3, to be published very shortly, and any description of these primary devices in Part I would therefore be mere repetition.

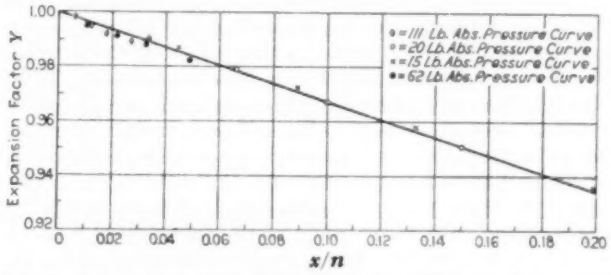

Fig. 4 Relation Between the Expansion Factor Y and the Acoustic Ratio x/n—Superheated Steam for 50 Per Cent Ratio Orifice

(r = ratio of differential pressure to absolute static pressure; n = ratio of specific heats—taken at 1.30 for superheated steam.)

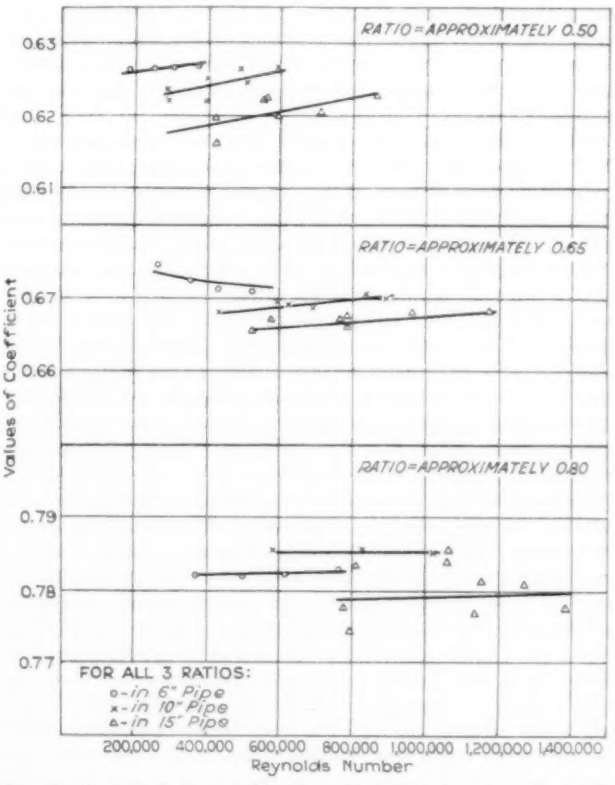

Fig. 5 Coefficients of Various Primary Devices Plotted Against Reynolds' Numbers

In the first sentence at the top of page 96, Mr. Smith states that the coefficient must therefore be a function of the Reynolds

[6] Engineering Department, The Brown Instrument Co., Philadelphia, Pa. Jun. A.S.M.E.

[7] Mechanical Engineer, Bailey Meter Co., Cleveland, Ohio. Assoc-Mem. A.S.M.E.

number only. Further attention is called to the fact that an identical coefficient will be obtained when complete geometric similarity of the shape of the differential producer and exact similarity of the flow through the producer are obtained. These statements, as the writer understands them, would indicate that the same ratio orifice, assuming that all points of design and conditions of flow are similar, would have the same absolute coefficient value regardless of pipe size. Fig. 5 shows graphically that such a relationship does not hold true, as shown by data obtained from hundreds of experiments conducted using steam and water as the flowing medium. The variation in coefficient for pipe size is quite appreciable, as will be noted from the curves, and is not covered by the Reynolds number. While it appears from data obtained at the Bailey Meter Company laboratory and also the Ohio State University laboratory, as well as from the data in Mr. Smith's paper, that the Reynolds number does serve a real need in ascertaining the correct coefficient of discharge of a fluid having entirely different properties as to pressure, temperature, and viscosity from that of a tested fluid, yet it does not hold that the Reynolds number includes the variation in coefficient due to change in the pipe diameter and that such data can only be obtained by experimental research.

In the second sentence at the top of page 100, Mr. Smith makes the statement that for a venturi tube or venturi nozzle the coefficient for a small diameter will be only slightly less than for larger diameters, since the additional friction increases the differential slightly. It is of interest that the coefficient of small-diameter flow nozzles is slightly larger than those for the large diameters. This holds true both as to variation in pipe size and in diameter ratio.

In discussing the application of orifices in the metering of dirty fluids or gases, the statement is made that there is more probability of erroneous coefficient being caused by deposits of material in front of the orifice, than would be the case where primary devices such as venturi tubes or flow nozzles are used. Further, statement is made that where wet steam is being metered there is a greater tendency for the entrained liquid to be thrown out of the steam and accumulate in front of the orifice, which might affect the coefficient. Attention is called to the fact that orifices can be made with the hole flush with the bottom of the pipe or so made that the only portion of the rim which projects inside the pipe is the segment which can be placed on top of pipe, either of which methods will eliminate the filling up of the pipe immediately in front of the orifice.

On the other hand, the orifice is a decidedly superior type of primary device in the use of metering dirty liquids or gases. On account of its relatively sharp edge, accumulations of extraneous matter will not form along the orifice edge, except possibly under the very worst conditions, and then not nearly as fast as in the case of a flow nozzle or a venturi tube. The use of pitot tubes or nozzle plugs is even more to be avoided than that of flow nozzles or tubes in the measurement of this type of fluid, on account of the rapidity with which the impact and static holes of the tubes become fouled in service. Mention is further made that venturi tubes are now provided with steam jackets for scavenging the throats of these tubes for naphthalene or tarry deposits. Attention is called to Fig. 6, in which the same idea is applied to an orifice installation.

It is noted that in Equation [69] Mr. Smith has included separate coefficients for friction and contraction, and further, that he has expressed the ratio R_c as referring to the diameter at the *vena contracta*. Such a formula for orifice design is extremely difficult to use. The writer sees no object in separating the various coefficients of discharge of an orifice into their component parts of friction, contraction, and other unknowns, nor does he deem it advisable to calculate the area ratio on the basis of the diameter of the *vena contracta*. A much simpler formula and one which can be applied quite readily in commercial design can be expressed as follows:

$$Q = CY \frac{1}{\sqrt{1 - r^4}} A\sqrt{2P/W}$$

in which C represents the coefficient of discharge, Y the expansion factor, r the ratio of the orifice hole to the diameter of the pipe on the inlet side, A the orifice area in square feet, P the differential pressure in poundals per square foot, and W the density of the fluid under the conditions at the inlet at the orifice. If gravitational units are not objectionable, as indeed they should not be in practically any condition, the above formula can be written as follows:

$$Q = CY \frac{1}{\sqrt{1 - r^4}} A\sqrt{2gH}$$

In this case g is the gravitational effect having a value of 32.174 and H is the differential head of the fluid at the density of the flowing conditions on the inlet side of the orifice. Such an equation reduces the unknown coefficient to one term C, and modifies this coefficient by the expansion factor Y in the case of compressible gases.

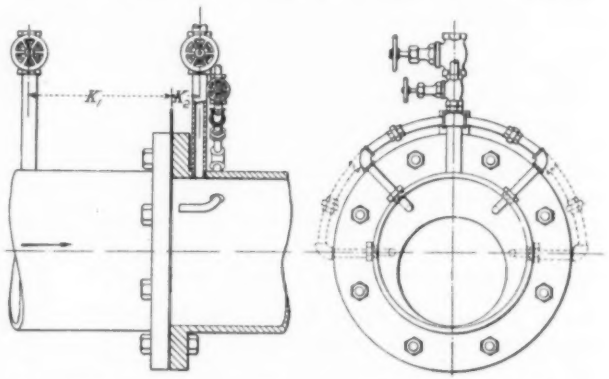

FIG. 6 STEAM JETS FOR CLEANING ORIFICES IN GAS LINES

A. J. NICHOLAS.[8] The writer hopes that he may be pardoned in digressing a little from the main topic of the papers by mentioning the work of the pioneers who initiated the steps that now bring us to our present concept of fluid flow and its measurement.

Stokes[9] in 1850 showed mathematically the factors that enter into fluid friction. Reynolds[10] in 1883 experimentally proved the critical points of fluid flow, showing where viscous and turbulent phenomena occurred. Lord Rayleigh[11] in 1892 proved Reynolds' experimental work to be mathematically correct. Stanton,[12] Bairstow, and Pannell in 1912 experimentally substantiated the mathematical concepts of Stokes and Rayleigh for flow in smooth and rough pipes. Stanton in 1917, while discussing Hodgson's[13] paper, suggested the plotting of meter coefficients on the basis of Reynolds' number. This Hodgson subsequently attempted in Figs. 32, 33, and 35 of his paper. These figures are undoubtedly the first published experimental coefficients plotted on the basis of dynamical similarity. A check of V_1D_1/U, which was used as the basis of plotting, shows it to

[12] Stanton, *Engrg.*, p. 437 (March 29, 1912).

[13] Hodgson, Min. Proc. Inst. C. E., vol. 204, part 2 (1916–1917).

be 10^2 too high, but the value of the work is nevertheless unimpaired if the multiplying factor of V_1D_1/U is 10^4 instead of 10^6 as given. Hodgson[14] realized this error shortly after the proofs had been passed and the paper had been published. Pannell[15] in 1919 anticipated a similar method of plotting coefficients for orifices, which unfortunately never materialized due to the untimely death which befell him shortly after as a passenger on a disastrous flight of a British dirigible. In discussing the Stanton orifice meter in his paper, for which geometrically similar orifices of 0.25 to 1.25 in. were available, Pannell stated, "The author hopes at some future date to publish these calibration figures and show that the results for the different orifices may be compared on a basis deduced from the principle of dynamical similarity." Hodgson[16,17] subsequently published orifice, nozzle, and venturi calibrations on this basis in 1921 and 1922. Since then this means has become more known and popular as a method of coordinating fluid flow.

With reference to Fig. 1 of Mr. Smith's paper, an omission of one of the important metering elements is noted, namely, the shaped nozzle. Such data are available from Hodgson's[18] paper for a complete range of Reynolds' number.

Hodgson,[19] in plotting coefficients as in Fig. 3 for similar types of orifices, has a straight line for ratios of 0.09 to 0.7, consisting of seven orifice ratios. Mr. Smith shows only three points, which seems to give a hump and a droop to the curve.

The significance of Equation [13] may be further amplified on the basis of Newton's second law. It is obvious that since the force is proportional to U and the mass of fluid per unit volume accelerated by this force is proportional to W, the accelerating effect will depend on the ratio U/W, i.e., force/mass, is proportional to acceleration. It is interesting to note that Maxwell was first to name this ratio U/W as the "kinematic coefficient" of viscosity, and the reason for it is obvious.

Mr. Smith states that gaseous flow at critical-pressure condition is generally known as Napier's relation. This relation is not generally known as such. Osborne Reynolds[20] was first to explain this phenomenon and showed that the velocity of the fluid leaving the metering element is equal to that with which sound is propagated in the fluid, so that any reduction in the back pressure cannot be communicated back against the stream.

It seems that Mr. Smith's Equation [25] is incorrect, which may be verified by the substitution of the fundamental units of mass, length, and time. These show that the equation as given is unbalanced by J. Equation [26], which follows, is correct, but cannot of course be arrived at from the preceding equation. Equation [25] is intended to be a form similar to Poiseuille's formula, which may readily be deduced by the method of dimensions in the form of $P_m = K_1 \frac{UV_m}{D_m}\left(\frac{VD_mW}{U}\right)^n$ so that $P_m = \frac{KUV_m}{D_m}$ from which Equation [26] naturally follows. It is interesting to note that for orifices and nozzles of short length, the discharge $Q_m = \frac{KD^3{}_mP_m}{U}$ where $K = f(R)$. Hodgson[21] deduces a modified equation for viscous flow on this basis, embodying the velocity of approach factors as in Mr. Smith's Equation [1]. The writer believes such an equation should be incorporated in the Committee's revised report, even though its field of usefulness for commercial metering purposes should be limited. Its usefulness in other fields of measurement cannot be overemphasized, such as, for example, research fields and the writer's own automotive work, where fluids are accurately metered in small quantities of varying viscosities in small-sized conduits.

In the writer's opinion the author's physical interpretation of Reynolds' number, flow similarity, and coefficients is unconvincing. A physical interpretation is no more convincing than a mathematical derivation properly diagnosed.

In connection with acoustic ratios the writer notes that in Mr. Smith's Fig. 5 relations are determined for steam with $n = 1.135$. This may be true for venturi tubes, but for orifices and nozzles it is more than likely that the expansion factor $n = 1.3$, based on the theory of supersaturation. Callendar[22] showed the discrepancy in flow through nozzles or orifices based on Zeuner's value of $n = 1.135$ and supersaturation theory with $n = 1.3$. There seems to be no doubt that quantity rate for nozzles or orifices should be based on $n = 1.3$, rather than 1.135. In the case of venturi tubes the value of $n = 1.135$ may be correct. Has Mr. Smith based the computations of Fig. 5 for the venturi on the assumption that Zeuner's value is correct, or was the value of n actually deduced by experiment with venturi tubes?

In conclusion the writer congratulates Mr. Smith on presenting a paper of great merit. It is a decided step toward standardization of all fluid meters on a common basis. In the writer's opinion it is an outstanding contribution on fluid meters.

STEPHEN E. SLOCUM.[23] The problem discussed in Mr. Spitzglass' paper concerns flow through pipes and orifices. This is of such a limited and special nature that the true significance of the hydraulic principles involved is not always apparent, and it may therefore add something to the discussion to consider the problem from a somewhat more general standpoint.

First of all, it seems necessary to confine the discussion to laminar or streamline flow, since it has been shown by experiment that turbulent flow in pipes follows quite different laws. So far as rational analysis is concerned, it must, for the present at least, be limited to laminar flow since the canonical laws of hydraulics are based on this state of motion.

Assuming laminar flow, geometrical similarity as defined in this paper is not necessarily equivalent to dynamical similarity, which is the proper basis for comparison. The writer is here considering the flow of a viscous fluid past a solid boundary, which in general may be either the surface of a solid immersed in the fluid or, as in the present case, the inside of a pipe wall. When the boundaries of two objects are identical in form but differ in scale or dimensions, then if l denotes the ratio of two homologous dimensions, such for instance as pipe diameters, in order for the conditions governing flow to be comparable, the following relations must be fulfilled:

Speed of advance (or relative velocity).....	$V = v\sqrt{l}$
Speed of revolution.....	$N = n \div \sqrt{l}$
Unit pressure.....	$P = pl^3$
Torque.....	$T = tl^4$
Power.....	$H = hl^{7/2}$

Solids geometrically similar in form, therefore, do not insure hydraulic similarity of flow, irrespective of size; or, stated conversely, dynamical similarity is a function of the relative scale of geometrically similar forms.

It is well known, however, that there are often apparent discrepancies in comparative results even when the laws of dynami-

cal similarity are satisfied. For example, in predicting the performance of a full-sized ship from model tests, the power required to drive the ship at a speed corresponding to that of the model, namely $V = v\sqrt{l}$, is often as much as 20 per cent greater than the corresponding power derived from the relation $P = pl^{7/2}$. This fact has long been recognized, but has recently been presented again as a result of experiments carried out in the Washington model tank as part of the present research program of the United States Shipping Board.[24]

The cause of such apparent discrepancy is probably to be looked for in the laws governing vortex formation arising from flow of a viscous fluid past a solid boundary. A viscous fluid, such as water or air, differs from an ideal fluid by the property that its retardation in the neighborhood of a solid boundary produces a steep velocity gradient which results in the formation of a vortex layer or sheet along the boundary. In the free fluid, viscosity effects are negligible, but in the neighborhood of a solid boundary they are of the same order of magnitude as inertia effects.

So-called frictional resistance in fluid flow along a boundary by no means resembles what we know as sliding friction. It is created rather by building up a vortex sheet along the boundary, which separates this boundary from laminar flow in the fluid itself. For example, in the case of a ship moving through the water, vortex sheets are formed along both sides of the vessel, which peel off from the stern on each side and persist behind the vessel, forming actual boundaries between the wake stream and the undisturbed water lying outside. It has been shown by Karman, Rehbach, and others that the resistance of an immersed body like a ship is a function of this vortex formation, depending jointly on the distance apart of the vortex sheets, the spacing or pitch of the vortex filaments in each sheet, and the strength of these vortex filaments. Very possibly the laws of vortex formation, on which resistance depends, are not directly related to the laws of dynamical similarity mentioned above, which would explain in whole or in part the discrepancy existing between model and full-scale results as now interpreted.

Rayleigh's law, VL/K = constant, where K denotes the kinematic viscosity (or Reynolds' number, as the left member is called), is certainly well established as the proper basis for the comparison of fluid flow. It is not so clear, however, that it applies without modification to the boundary layer, or vortex sheet, adjacent to a pipe wall. As mentioned above, the viscosity effects in the neighborhood of a boundary are of the same order of magnitude as inertia effects, and as the size of pipe decreases, these necessarily become of greater relative importance in their effect on discharge.

A valuable feature of the Reynolds number is that it makes it possible to apply the extensive data obtained in aeronautics directly to hydraulic problems. Thus if the subscript w in the following relation applies to water, and the subscript a to air, Rayleigh's law becomes

$$V_w L_w = \frac{1}{13} V_a L_a$$

By means of this numerical relation one is thus enabled to apply many of the results derived from wind-tunnel tests directly to marine practice. In particular, one can pick out from the innumerable airfoil shapes that have been tested those which are most suitable for blade sections of marine propellers or of hydraulic turbines.

The exceptions cited in Mr. Spitzglass' paper, therefore, do not discredit existing hydraulic laws, but reveal their limitations and indicate the need for further research in the domain of vortex phenomena, which has proved such a fertile field for investigation in the hands of scientists like Prandtl.

DR. RUDOLF WITTE.[25] As long as the effect of friction on flow measurement cannot be mastered by mathematics, that effect must be determined experimentally and must be presented by an empirical coefficient. For the comparison of individual measurements we have, for the time being, only the mechanics of similarity at our disposal. These teach us that a result obtained under a given research condition is applicable also to other conditions when there are definite relations between the dimensions of the magnitudes involved. They also teach us how the research data can be presented (namely, as a function of the so-determined dimensionless characteristics) so that the results may be extended beyond the scope of the original data.

For flow in closed pipes the fundamental hydraulic equations of Euler-Stokes are applicable:

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + w\frac{\partial u}{\partial t} = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \frac{\mu}{\rho}\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial u^2} + \frac{\partial^2 u}{\partial t^2}\right)$$

p = pressure, ρ = density, μ = viscosity

These equations apply equally for liquids and gases as long as the change in density with the change in pressure and temperature can be ignored—also for adiabatic phenomena where the expansion is not significant. We must also bear in mind that such possible outside energy influences as weight, capillarity, and compressibility are not considered in the relation, and these must not have any influence. The forces which appear under such simplified assumptions in the Euler-Stokes fundamental equations are of various types (inertia forces, friction forces, pressure drops): if in general the lengths are changed in a definite proportion f_l, if the velocities are changed in another definite proportion f_w, and—transferring to another fluid—if the density and viscosity are changed in a similar way in the proportion of f_ρ and f_μ, respectively (that is, all the fundamental dimensions which are involved), then each one of the forces assumes a dimensionless factor which can be constructed from the four scale relations:

$$\frac{f_\rho f_w^2}{f_l}, \quad \frac{f_\rho}{f_l}, \quad \frac{f_w f_w}{f_l^2}$$

By equating these various factors we arrive at the limiting conditions under which the equations remain true; that is, under which the forces remain in equilibrium:

$$f_w = \frac{f_w}{f_\rho f_l}, \text{ or } \frac{l_1 w_1 \rho_1}{\mu_1} = \frac{l_2 w_2 \rho_2}{\mu_2}$$

We then find that the limiting condition is the so-called Reynolds characteristic, according to which the relation of diameter times velocity, divided by kinematic viscosity, must remain constant. When the measuring installation is changed so that it is geometrically similar, then the velocity must be changed in inverse proportion to the lengths, or if the fluid is changed, the velocity must be changed directly with the viscosity. Following this and *by strictly adhering to the given assumptions* one must absolutely demand the same dimensionless coefficient for equal values of Reynolds' function in the case of restricted openings. In practice, however, we cannot strictly adhere to these assumptions, and only experiment can determine the practical deviations from the general rule.

From this standpoint the writer has carried through, in his publication of 1928, an examination of the application of the laws of similarity, with the result that for one and the same restricted opening in the same pipe the law of similarity holds true within

[24] *Marine Engineering and Shipping Age*, March, 1930, p. 145.

[25] Ludwigshafen am Rhein, Germany.

one per cent—for water, oil, steam, and air—and that in the case of the orifice plates when the pipe diameter is changed the law of similarity does not hold—as Spitzglass has shown before. From this deviation of the law of similarity the writer came to the conclusion that in the respective orifice coefficients there exists another unknown influence, and he undertook the task of discovering this influence and thereby explain the dependence of the coefficient upon the size of the diameter. In another work, which has been in the hands of the V.D.I. since the middle of September and which will be published in January, 1930, he has accomplished this with the results that when strictly adhering to the geometrical similarity of the orifice plate and the pipe wall surface, the laws of similarity apply exactly for various pipe diameters, because he has obtained *for pipe diameters from 500 to 1000 mm. exactly the same coefficients* for the same orifice ratios. In the case of ordinary rough pipes the requirements for geometrical similarity are not fulfilled, and in fact this has a considerable influence on diameters under 300 mm. Then it is also possible that in the case of rough pipes and small diameters the limits are not the same for liquids as for gases. (With reference to the limiting film on which the surface forces are acting.) For this the writer has conducted further very careful calibration tests with air and then even in the small diameter of 50 mm. he found the laws of similarity correct. It is understood that according to the above limitations on the derivation of the Reynolds characteristics the coefficient for water can be applied to air only if we neglect small changes in density. For larger expansions (differentials in gas measurement) there is nothing definite that the law of similarity can show about the coefficient, and in fact the coefficient is different at larger differentials.

In many cases the Reynolds function becomes a *necessity* for presenting measurement data. The presentation of data on the basis of velocity is at least not entirely correct—because when the temperature changes (change in viscosity) there is at the same velocity a change in the coefficient far into the region of turbulent flow. For rough pipes this theory is not yet completed. The application of the law of similarity for rough pipes is yet to be established.

The writer believes, therefore, that the various laws of similarity are actual laws which hold for the assumptions for which they are derived. Any deviation in the experiments with models must be attributed to the insufficient fulfilment of similarity requirements. In studying these deviations—as for instance the diameter influence on the orifice coefficient—we learn new influences which must be corrected for in the methods of fluid measurement.

Dr. Max Jakob.[26] I have noted with much interest the exceedingly fundamental outline of historical development in Mr. Spitzglass' paper. In addition I have the following to say: I have not at hand the titles of Odquist and Härlin's works to which we (Jakob and Kretschmer) referred in the recent bulletin. I call your attention especially to Equations 22–24 in our bulletin.

As regards the principle of similarity, it appears to me to be in the following state: This principle is correct; it must, however, be correctly applied, that is, it is necessary to take into consideration not only the similarity of the Reynolds number but also all other requirements of similarity. For instance, there is involved, through the roughness of the pipe, at least one more quotient of two lengths; namely, the mean height of the obstruction and of the diameter. Inasmuch as the obstructions are generally not geometrically similar, it is absolutely necessary to look for other parameters in order to take care of the roughness. Therefore, in practice it is very hard to compare the roughness of various pipes, and in this I see the fundamental reason for the differences in the results of various observers. It is necessary, for example, with gases, as Odquist and others have shown, to include another parameter consisting of two ratios, one the ratio of the mean velocity to the velocity of sound in the medium, and the other the ratio of the specific heat at constant pressure to the specific heat at constant volume. The difference in the observations on water and air, for instance, depend on these items which are not fully explained as yet. In a word, there is no doubt about the principle of similarity, but under the circumstances it is very doubtful whether similarity can be fully applied and taken into consideration.

We have in preparation a new and most interesting contribution from Dr. Witte which will be published in the first issue of the magazine *Technische Mechanik und Thermodynamik*, of which I am the editor. Witte's work deals with additional measurements at the I. G. Farbenindustrie on orifice plates and nozzles, and in this work the question of similarity is advanced forward a considerable step. The contribution will be published in the January and February (1930) issues of the new magazine.

Alton C. Chick.[27] The three papers presented in this symposium bring our attention very forcibly to the present method of analyzing fluid flow in closed conduits, namely, correlating it with the dimensionless ratio involving a linear dimension characterizing the shape, the velocity of flow, and the kinematic viscosity of the fluid, generally termed the Reynolds number.

The method used by Mr. Smith in showing how the Reynolds number is related to the flow distribution, by means of the nozzle and capillary tube in parallel, is very interesting. It gives the basis for the relationship and helps one to obtain a clearer understanding of the physical meaning of the Reynolds number itself.

Mr. Smith has succeeded in placing the venturi meter and the orifice meter on the same practical working basis by means of the Reynolds number and the acoustic ratio—two dimensionless ratios, and has given the results of a considerable number of published experiments to illustrate his method.

His development of the acoustic ratio lays down a new and very simple operator for use in the metering of gaseous fluids that promises to play as important a rôle as has the Reynolds number in metering viscous fluids. He has presented a simple straight-line correction formula for the effect of expansion, which ties his theory with present data. This has greatly simplified the mathematics involved in the commercial metering of fluids.

In appendixes Mr. Smith touches upon the basic theory of fluid flow, giving a clear discussion of viscosity and the law of dimensional homogeneity as applied to fluid flow.

Messrs. Beitler and Bucher have presented the results of practical tests of orifices in six-inch pipes which check with values of correction factors and coefficients obtained by Mr. Smith, thus further establishing the usefulness of this method of analysis.

Mr. Spitzglass has presented an interesting historical discussion of the development of some of our present hydraulic equations, but there appears to be a difference of opinion concerning the application of the principle of similarity to experiments with fluids, using small-scale structures. Mr. Spitzglass erroneously gives one to understand that the Reynolds number is not a criterion of similarity in the régime of turbulent flow, and that there is an effect or size (which in the case of a pipe, would be the diameter) which is unaccounted for when different sizes of similar models and prototypes are tested.

Actually in the case of closed conduits the use of the Reynolds number implies and requires that the model and prototype be geometrically similar in all respects including the roughness of the interior walls, and that as has been shown by several authori-

[26] Berlin, Germany. From a letter received by Mr. Spitzglass.

[27] Assistant Engineer to John R. Freeman, Providence, R. I. Jun. A.S.M.E.

ties,[28] the Reynolds number is the *only* criterion necessary for complete similarity. In the case of open channels, where the surface is exposed to the atmosphere, other factors are involved such as gravity and surface tension which bring into account other dimensionless ratios such as Froude's number, usually expressed as Lg/v^2, etc.[29] In the case of a closed pipe, if the interior roughness of a large pipe is not similar to that of a smaller-scale pipe which in other respects is geometrically similar, then it has been shown[29] by dimensional reasoning that if we could express the size of the irregularities by a simple linear quantity such as ϵ, then the coefficient would be not only a function of the Reynolds number but also a function of ϵ/d, where d is the diameter of the pipe.

We should not be led to condemn the validity of such a relationship as the Reynolds number simply because it may be impracticable commercially to construct structures of different sizes that will have their interior surfaces *exactly* geometrically similar. This apparent scale effect, the writer believes, is due only to the lack of precision in making the model and prototype truly similar, and this has been adequately discussed in the present paper by Mr. Smith. In his 1923 paper on the oil venturi meter, it was shown for the first time, the writer believes, that there was a slight scale effect on the coefficient, when plotted against the Reynolds number, resulting from the difference in velocity distribution in the pipe at the inlet and a difference in the loss caused by friction between the inlet and the throat, due to the roughness not being geometrically similar in the various sizes of pipes and throats.

When we do have geometrical similarity between the roughnesses in model and prototype then the coefficients will be identical, as Mr. Smith points out. This has been established by many experiments in European hydraulic laboratories which have been performed to test the validity of the laws of similarity.[30] Experiments by B. F. Groat,[31] one of the first in this country to make use of the laws of similarity in testing models of hydraulic structures, with models of ice-diversion structures for the St. Lawrence River, caused him to conclude that "there was nothing in the results of the experiments to indicate that they (the models) did not perform *exactly* as their prototypes."

Finally, the writer wishes to emphasize the necessity of having the approach and exit conditions at the model geometrically similar to the approach and exit conditions for the prototype in order to insure similarity of flow in the structure itself. If these conditions are not properly duplicated then the velocity distribution will be different, and an *apparent* scale effect will be found in the results.

All over the world today, and especially in Europe, a great amount of experimentation is being done on small-scale models in hydraulic laboratories. The principle of similarity applied to fluid flow is constantly being tested for all types of structures, for closed conduits as well as for open channels. The present papers are a notable addition to our knowledge of this subject.

ED S. SMITH, JR. The paper by Messrs. Beitler and Bucher shows evidence of high-grade experimental work, the essential data of which are confirmatory of previously established facts. In their paragraph referring to their Fig. 20, it should be remembered that the A.S.M.E. compressibility factor applies to nozzles having fixed non-expansible throats, and not to cases of orifice flow where the *vena contracta* itself is highly expansible. This point is discussed in the writer's closure to his paper which is a part of this symposium.

For example, their Fig. 20 for steam and the accompanying discussion are confirmatory of the writer's Fig. 2, presenting data from U. S. Bur. of Stds. R.P. 49 for air. The actual expansion factor Y for orifices is definitely established within small limits. Mr. Spitzglass similarly published Fig. 26 on page 324 of the discussion of Hodgson's 1928 A.S.M.E. paper,[32] which is confirmatory of Beitler-Bucher's Fig. 20. The deviation of the actual Y from the theoretical value Y_t of the expansion factor for orifices is highly important, and the writer welcomes its frequent mention.

R. Bachmann, of Darmstadt, in 1912 brought out data on this point. Hodgson's 1917 equation $C'' = 0.914 - 0.306\ P_2 / P_1$ for the coefficient C'' for orifices for gas (to be used with the theoretical expansion factor Y_t) clearly brings out the point that the theoretical expansion factor Y_t is excessive. There has been considerable progress since 1912 and the actual expansion factor Y for the usual concentric orifices having diameter ratios up to 0.6 (as well as for venturi tubes and nozzles) is at present known to within a few tenths of one per cent for any gaseous fluid with any usual differential pressure ratio.

The writer suggests the general use of the term "turbulence ratio" (symbol R) instead of the Reynolds number including cases where the orifice diameter is used instead of the pipe diameter. This term is highly descriptive and may well be abbreviated in actual use to the single word "turbulence."

The correction for the weight of air over a water column is also an established part of the writer's fluid-meter calibration and manufacture practice for precision fluid measurement. The writer has long dealt with fluid metering on the mass-flow basis instead of the weight-flow basis in which the values are affected by the weight of air. A complete sample computation involving air-weight correction factor would form a valuable addition to the appendix of the paper by Messrs. Beitler and Bucher.

Orifices of different ratios actually constitute different "shapes" and each shape necessarily requires calibration. In regard to the authors' statement in the third paragraph from the end of their paper, it is pointed out that the use of the Reynolds number in fluid flow requires that the shapes be geometrically similar. Data for wet steam would be an important extension of this work.

Mr. Spitzglass urges the need for caution in the application of the general method of similarity and the Reynolds number to fluid metering, especially in regard to its adoption as a law, for meters for various sizes of pipes.

In his 1923 A.S.M.E. paper,[33] "The Oil Venturi Meter," the writer published data for various sizes of venturi tubes having the same absolute roughness in which the coefficient was plotted against the Reynolds number, clearly showing the "scale" effect, the smaller venturi tubes having slightly lower coefficients than the larger. The correlation between coefficient and the Reynolds number for any given meter was definitely and unquestionably established not only for viscous streamline flow but also for turbulent flow. The scale effect was shown to be relatively small for the usual commercial sizes. This scale effect was clearly stated as being simply the slight departure of the shape, due to roughness, from exact geometrical similarity of otherwise similar venturi tubes. Since these venturi tubes had the same absolute roughness it is obvious that the smaller tubes were rela-

[28] Lindquist, Erik, "Am Modellregler eller Lekformighetssatser vid Vattenbyggnadstekniska Förösk" (The Laws of Similitude for Model Tests on Hydraulic Structures), *Teknisk Tidskrift*, Stockholm, 1925. Nos. 30, 34, and 43.

[33] Trans. A.S.M.E., vol. 45 (1923), pp. 67–75.

tively rougher than the larger tubes, and indeed the effect of this slightly greater relative roughness was reflected in their slightly lowered coefficients.

The method of similarity, as used by the writer at that time, has come into increasing use, since it is an efficient method for correlating and using data: for any given size and shape of differential producer, the coefficient may be determined with any convenient fluid plotted against the Reynolds number, and then used with certainty for metering any other known fluid. Numerous experiments have established the fact that the deviations from exact geometrical similarity due to scale effect (relation between pipe size and relative roughness) are shown by the coefficient to be relatively slight—a mere "vernier" correction for the more usual differential producers. The use of the Reynolds number as a rigorous basis for correlating coefficients with turbulent and viscous flow has been established by the actual experimental work of Stanton and Pannell on friction loss in pipes, and by Hodgson, Daugherty, the writer, and numerous others, on various fluid meters.

The method of similarity (involving the use of the Reynolds number in determining flow) is not based upon any assumption. It is derived simply from the fact that certain variables are involved in fluid flow, and hence are known as "pertinent." From the simple obvious requirement that the dimensional units on each side of any true equation must be identical, a formula is obtained directly which merely has the pertinent variables in their proper relation, and the empirical dimensionless constant must be established by actual calibration. This formula is inevitably rigorous when it includes all of the pertinent variables, and no others.

For the flow of liquids in closed conduits, this method shows that the coefficients for differential producers of geometrically similar shapes depend only upon the Reynolds number when the pertinent variables are the velocity, density, and viscosity of the fluid and any corresponding linear dimension, such as diameter, of the conduit. Repeated indisputable calibrations with various liquids have established the fact that the coefficient is a function of the Reynolds number only, within the limits of experimental error. This proves that the Reynolds number includes all of the pertinent variables, and no others, affecting the coefficient, and directly confirms the fact that absolutely no assumptions are involved. This is not a mere matter of belief but of proof, i.e., *this method works*.

Roughness is an essential part of the shape of a differential producer; a basic element of the theory of similarity. The lack of an absolute measure of roughness has vexed hydraulicians up to the present, and even now constitutes the subject receiving the most consideration. The best expression of relative roughness which has yet been devised is probably simply the ratio of the height e of the rugosities to the pipe diameter d, thus e/d, which accurately takes account of the diameter effect for pipes of the same absolute roughness. However this ratio is not complete as a general basis since the shape of the rugosities and their pattern certainly affect the "shape" of the roughness.

First consider a situation where practically geometrically similar shapes produce substantially true hydraulic similarity, irrespective of size—in other words, the absolute size of the pipe does not appreciably affect the coefficient except as it enters the Reynolds number. Such a situation is not difficult to arrange, in fact it can be simply obtained, within commercially acceptable limits of error for the various sizes generally used, by using an orifice with flange taps and with velocity-equalizing "straightening vanes" similarly located upstream of the orifice, as Bean's recent experiments (referred to by Dr. Buckingham) clearly establish.

Now consider another situation involving orifices with the connections located one diameter upstream and at the *vena contracta*, as used by Spitzglass, where nominally "similar" orifices (of identical diameter ratios) in 4-in. relatively rough pipes have slightly higher coefficients for the same Reynolds number than in 8-in. relatively smooth pipes. Mr. Spitzglass maintains, the writer understands from his paper, (1) that hydraulic similarity does not (necessarily) exist in various sizes for equal Reynolds' numbers even though exact geometrical similarity does exist, and (2) that the coefficient is a function of the absolute size of the pipe (not of the shape, including the roughness). However, the writer would like to point out (1) that the absolute size of the pipe only enters in the Reynolds number and in the shape in so far as it affects the pipe's relative roughness, (2) that roughness is as truly a part of the pipe's shape as its general roundness, (3) that, consequently, small pipes are thus not exactly geometrically similar to large pipes having the same absolute roughness, and (4) that since the geometrical similarity is not exact in such small and large pipes, exact hydraulic similarity is not required by the law of similarity to exist with identical Reynolds' numbers.

Mr. Spitzglass seems to have overlooked the material on the "scale effect" in the closure of Mr. Hodgson's 1928 A.S.M.E. paper. Mr. Hodgson is in a position to have access to many full-scale calibrations of a variety of orifices upon numerous fluids.

Dye clouds passing through an orifice distinctly show the profiles shown in the writer's Fig. 3 or in Spitzglass' upper Fig. 10, which is labeled "incorrect." Spitzglass' lower Fig. 10, which is marked "correct," merely shows where turbulence exists. The writer suggests that a composite diagram, similar to his own Fig. 10, would be more satisfactory, showing the "dynamic streamlines" (mean flow direction), velocity-distribution traverses (mean velocity magnitude), with curls showing where eddies occur. At best any static diagram of transient flow phenomena is inadequate, slow-motion pictures such as Baron Shiba's A.S.M.E. film, showing the moving particles, are really required.

Finally, Mr. Spitzglass bases a "variation of coefficient with absolute size of the pipe" upon an assumed pipe-friction effect (incomplete boundary flow concept) which is not in accordance with the findings of Gibson[34] and others that for small and large smooth (practically geometrically similar) pipes the velocity distribution is the same for identical Reynolds' numbers.

Also, on Mr. Spitzglass' page 117, he seeks to base the variation of the coefficient with absolute pipe diameter upon Odquist's work, which was shown to be fallacious upon the writer's page 96.

Authors' Closures

S. R. Beitler and Paul Bucher. The authors are grateful to those who have discussed their paper and offered criticisms which may be useful in the continuation of this work. This continuation is proceeding at a very satisfactory rate, and it is hoped that the final results will be available for publication by the end of 1931. A much more complete paper covering the work done to date will appear as a Bulletin of the Engineering Experiment Station of the Ohio State University about the first of March, 1931.

For the information of Mr. Gess, condenser leakage tests were a matter of weekly routine in the laboratory.

Mr. Conlee's discussion on the location of the *vena contracta* is of much value. In the continuation of our work a change has been made in the method of taking the pressure and a smaller opening into the pipe is used. It was felt that this would give

[34] "The Principle of Dynamical Similarity, With Special Reference to Model Experiments," by A. H. Gibson, *Engineering*, March 14, 1924, p. 327. "In the smooth pipes, identical (velocity distribution) curves were obtained . . . when the Reynolds number was the same in each pipe, one being 4.93 and the other 7.40 cm. diameter."

more accurate results where the flat portion of the *vena contracta* was relatively short.

Dr. Moss's criticism of the orifice versus the flow nozzle is a question which is yet unsettled in the opinion of the authors. However, the fact that for commercial purposes it is necessary to use comparatively large-ratio nozzles, which Dr. Moss does not advocate, has some bearing in the matter. The additional data which have been collected but not as yet completely analyzed nor published cover both orifices and nozzles in all practical ratios and should help to settle this question.

Mr. Smith requests that a complete sample calculation involving the air-density correction to the differential head be added to the appendix. This request is denied at this time due to lack of time only and will be granted in the later publication already mentioned in this closure.

Ed S. Smith, Jr. The author's paper was presented in order to place the available information on fluid metering in shape to attract criticism so that the material would either be confirmed or rejected as a basis for the revision of the Fluid Meter Report.

Mr. Conlee's desire for data on meters on the different commercial pipe sizes is certainly shared by the "advocates of similarity." After all, similarity merely enables one to make the best use of data, since it permits the data for the various sizes to be placed upon a common rational basis.

Flange taps generally have been in better agreement with test results than have published data upon the *vena-contracta* taps, according to studies available to the author, and have the advantage that they are more flexible since it is not necessary to change them whenever an orifice is changed. Authorities fail to agree on the location of the *vena contracta:* while the Beitler-Bucher data agree closely with those of Johansen in the Hodgson paper,[35] the Spitzglass data would indicate that the *vena contracta* is 0.7 diameter from the orifice instead of 0.9 as Johansen shows for $d/D = 0.4$. Furthermore, at high differentials, Buckingham affirms that the *vena contracta* blows further downstream with gaseous fluids. The flange taps favor the use of the annulus which is ideal with concentric orifices in avoiding the effects of local pipe-surface irregularities and accidental eccentric installation of the orifices; of course, for the highest flows, segmental or eccentric orifices may be used with the simple flange taps with reliable results.

Although Mr. Conlee's use of the venturi expansion correction factor has been disproved for orifices, his use of it brings out the need for more published data upon high-ratio orifices with gaseous fluids. The acoustic ratio will permit the correlation of such data based upon various gaseous fluids so that this field will be most quickly covered.

The author concurs with Dr. Moss that the standard venturi tube or nozzle offers the highest accuracy which can be relied upon; however, for those who find it necessary to use orifices in metering gaseous fluids, the acoustic ratio was offered as a proper basis for the actual expansion factor Y, or for CY, which Dr. Moss suggests will prove more convenient. In correspondence with the author Dr. Moss independently confirms the validity of the acoustic ratio.

Mr. Gess confirms the aim of the paper as to its form, which was to place orifices and venturi meters upon a common basis with the simplest possible method of use, followed by adequate theoretical justification of this basis.

The author greatly appreciates Sprenkle's study and discussion, presenting the Beitler-Bucher orifice expansion-factor data for steam plotted upon the acoustic ratio x/n, which by its remarkably close agreement with the data on air from U. S. Bur. of Stds. R.P. 49, similarly plotted on the author's Fig. 2, strikingly confirms the use of this acoustic ratio.

Sprenkle's straight-line expansion factor for steam agrees with the data on air for similar taps, when plotted upon the acoustic-ratio basis—the average difference being only about one-tenth of one per cent. Bean's more recent data on natural gas definitely confirms the straight-line relation, and consequently the straight-line formula, when used with proper constants, as shown on the author's Fig. 4. The remarkably close agreement between the expansion factor Y data on steam, air, and gas by separate experimenters commends the work of all and also shows the validity of the acoustic ratio as the basis of correlation.

Ruppel,[36] in a recent paper on the effect of expansion on the *vena contracta* of orifices, presents an interesting computation of the expansion effect for orifices which checks very closely with both the air and steam data referred to above. The relation is seen to be very nearly a straight-line one, and the computation is along the lines of the author's Chapter VI, except that Ruppel goes further and computes the actual expansion of the *vena-contracta* diameter upon the assumption that its expansion also follows purely adiabatic laws. Ruppel computes values for both air and steam which are found to be practically

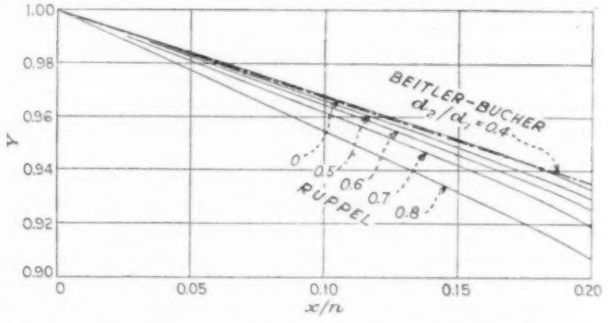

Fig. 2a For Throat Taps. Relation Between Expansion Factor Y and $1 - (P_2/P_1)^{1/n}$

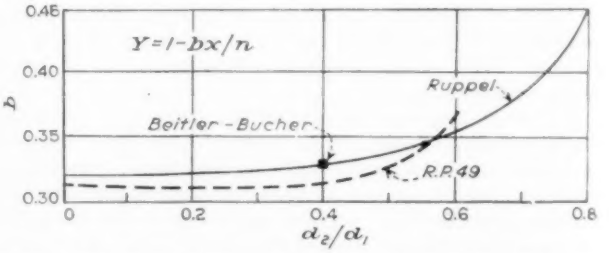

Fig. 4a For Throat Taps (Based on $x/n = 0.10$). Relation Between Expansion Constant b and Diameter Ratio d_2/d_1

identical when both are plotted against the author's acoustic ratio. His values and those of Messrs. Beitler and Bucher and U. S. Bur. of Stds. R.P. 49 are shown on the accompanying Figs. 2*a* and 4*a* to be almost unbelievably confirmatory of each other and of the validity of the acoustic ratio. Ruppel also uses the hydraulic formula (in a slightly modified form) and brings out the advantage that one may calibrate an orifice with water at corresponding Reynolds' numbers and then use the coefficient with air or steam with greater exactness than the coefficient can generally be obtained with equal ease on the gaseous fluid itself, confirming the author's method.

[35] Trans. A.S.M.E., paper No. FSP-51-42, p. 324.

[36] G. Ruppel, "Effect of the Expansion on the Contraction beyond Orifices." Berlin-Siemenstadt, Technische Mechanik und Thermodynamik, vol. 1 (1930), pp. 151–157.

In accurately metering hot fluids such as steam, while using a coefficient C obtained with a cold liquid such as water (and the proper expansion factor Y), it is necessary to consider the expansion due to temperature of the orifice plate or venturi throat, the area expansion in per cent at 500 deg. fahr. being as follows, other temperatures readily interpolated:

cast iron	0.48
cast steel	0.57
cast hard bronze	0.83
cast brass	0.88

Consideration of this expansion may serve to bring the experimental values for steam into closer agreement with those of air. This correction has long been used with venturi meters, see "The Venturi Meter as an Instrument for the Measurement of Liquids and Gases," by F. G. Gasche and R. S. Younglove, Illinois Steel Company, 1911.

The author's paper presents a method, not data, and this is clearly stated in the Introduction: "The data presented are purely for illustrating the use of this method." However, the author submits that his method shows data from reliable sources to be mutually confirmatory, and he welcomes the publication of such data. Sprenkle's Fig. 5 shows a lack of flatness of the coefficient at high Reynolds' numbers, which is foreign to the author's experience. Data plotted to such a large scale occasionally seems to indicate tendencies beyond the actual accuracy of the laboratory. Numerous coefficient graphs obtained by Pardoe at the University of Pennsylvania hydraulic laboratory, show that the coefficients are substantially flat at the Reynolds numbers covered by Sprenkle's data.

Sprenkle's Fig. 5 indicates that pipe roughness is really part of the shape of a differential producer, large pipes being generally relatively less rough than small pipes, and that it is consequently necessary to calibrate differential producers in the various commercial sizes of lines, since the Reynolds number only brings out flow similarity in geometrically similar shapes.

The author's experience on meters for wet steam and dirty fluids containing segmental orifices shows that while such orifices are generally excellent, they provide the basis for the author's remarks, which are confirmed by reference to Fig. 2551 of "Principles and Practice of Flow Meter Engineering," by the Foxboro Company. The author's first paragraph on "Dirty Fluids," page 101, comparing orifice and nozzle performance, seems adequately to cover Mr. Sprenkle's discussion on this point.

Sprenkle's formulas proposed for use with orifices are seen to be equivalent forms of the author's Formula [1], likewise intended for commercial use with both orifice and venturi meters. The author's Chapter VI presents an orifice analysis, like Chapter V for the venturi tube, which contains the heading that these two chapters are "merely illustrative material, offered as being of general interest." Thus, while the author's Equation [69] shows those interested that which occurs in flow through orifices, it was not recommended for commercial use. However, the great results which Ruppel has achieved through the extension of such an analysis more than justify him in its presentation.

In substance, Sprenkle's discussion seems to be generally confirmatory of the author's material.

Mr. Nicholas' historical summary could well be extended to include Helmholtz.[37]

As Mr. Nicholas observes, there is actually a "hump and a droop" of the coefficient in the author's Fig. 3, as confirmed by U. S. Bur. of Stds. R.P. 49 and Hodgson's Fig. 7 in his paper No. 31 of Mr. Nicholas' reference 21. The writer's "three" points represent the mean of a considerable number of tests with water in a 6-in. pipe.

Mr. Nicholas' physical interpretation of the kinematic viscosity as an acceleration is interesting but the dimensional units are L^2/T and not L/T^2, those of acceleration. In regard to the author's physical illustration of the Reynolds number as applied to flow similarity and coefficients, the physical reality seems more important than the mathematics, which is a mere tool that must be guided by the physical analysis. The history of hydrodynamics has repeatedly shown the limitations of purely mathematical analyses as opposed to those accompanied by insight into the actual physical situation.

Mr. Nicholas' criticism of the author's reference to the law of gaseous-fluid flow at the critical-pressure condition as Napier's relation seems unsustained in view of its use for the steam flow at this condition according to Marks' "Mechanical Engineers Handbook," and Hirshfeld and Barnard's "Heat-Power Engineering," both of which are representative of American practice.

The author prefers to use physically descriptive terms instead of proper names for engineering quantities as far as possible without departing seriously from current usage. If this critical-pressure relation should bear the name of Reynolds, as inferred by Nicholas, confusion with the well-known Reynolds number might result. However, the latter is being loosely used at present with the venturi-tube throat or orifice diameter instead of the pipe diameter. Hodgson prefers to call VDW/U the Rayleigh number, while B. F. Groat insists that it is properly the Stokes number. To avoid such confusion, the physically descriptive term turbulence (using the symbol R), which Nicholas used in a recent fluid-meter paper, is preferred by the writer, who proposed it in his 1923 paper on metering oil. In line with this reasoning, the author christened x/n the acoustic ratio.

In his discussion of the author's Equation [25], Mr. Nicholas failed to note that the author's J is a pure number, being the number of diameters the tube is long, and not the length in dimensional units.

Mr. Nicholas offers a suggestion that his viscous-flow equation, equivalent to the author's Equation [26], be included in the revision of the Fluid Meter Report. He suggests that it not only be corrected for velocity of approach as in the Hodgson reference, but it also be considered that the proper velocity-head with viscous flow is V^2/g instead of the usual $V^2/2g$.

As a matter of fact, the author nowhere in his paper has stated that the value of n is 1.135 for steam, although this value was formerly used generally for metering wet steam. All numerical values given throughout the paper are merely to illustrate the method, and the values of n from 1.135 to 1.67 were offered to cover any possible range of values. However, in answer to Mr. Nicholas' question, the proper value of n for superheated steam is unquestionably near 1.3 and this value also holds closely for wet steam, as established by the Callendar reference, while it is in substantially adiabatic rapid flow through venturi tubes, nozzles, or orifices. Although the performance of commercial steam meters, with n as 1.3, has been confirmed by weighed water tests, still more data are naturally to be desired. The remarkably close agreement of the Beitler-Bucher steam data with the U. S. Bur. of Stds. R.P. 49 air data is also confirmatory of the use of 1.3 for superheated steam. The use of various values of n for air recommended by various authorities is noted: 1.3947 for "normal" air, Moss; 1.40–1.402, Buckingham; 1.408 (the formerly generally accepted value), Hodgson.

Acknowledgment is gladly made to Mr. Hodgson for his correspondence containing the following simple derivation of the acoustic ratio as an approximation of the adiabatic-flow formula, which is an important independent verification of its validity:

"The adiabatic criterion for flow is

[37] See "Wissenschaftliche Abhandlungen," vol. I, p. 185.

$$\frac{(P_1/P_2)^{(n-1)/n} - 1}{(n-1)\,[1 - (d/D)^4\,(P_2/P_1)^{2/n}]} \quad \ldots\ldots [1]$$

By substituting

$$P_2/P_1 = 1 - h/P_1 = 1 - x \quad \ldots\ldots [2]$$

in [1] and expanding, the first term becomes

$$\frac{1}{1 - (d/D)^4}\,\frac{x}{n} \quad \ldots\ldots [3]$$

and when d/D approaches zero, or for any given shape d/D with geometrically similar meters, the approximate flow criterion is simply

$$x/n \quad \ldots\ldots [4]$$

which is the basis adopted by Mr. Smith, and termed the acoustic ratio.

"A further simple elastic-flow criterion, which will be found to be very suitable for correlating experimental data, may be deduced from the assumption that, for similar conditions for different fluids, the ratio of velocities V_1/V_2 must have the same value. This is equivalent to saying that the ratio of densities W_2/W_1 must be constant for each case compared; so that, if the expansion is adiabatic, the elastic-flow criterion may be written:

$$\left(\frac{P_2}{P_1}\right)^{1/n}$$

"Actually $(P_2/P_1)^{1/n}$ is the most accurate of the various approximate flow criteria listed.

"The criterion P_2/P_1 was used throughout the author's own paper because it was the simplest in the above list, and because it was found convenient to plot the various curves against P_2/P_1 as this term occurs in the general discharge formula."[38]

Comparison of Hodgson's $(P_2/P_1)^{1/n}$ with the author's acoustic ratio x/n shows that, within the usual commercial range of conditions, there is no appreciable difference in the results obtained from the use of these two operators. Only a few tenths of one per cent difference exists between expansion factors determined by each with the usual range of gases of $n = 1.2$ to 1.4 up to an acoustic ratio of $x/n = 0.3$ for concentric orifices of 0 to 0.75 diameter ratio and $x/n = 0.2$ for nozzles of 0 to 0.5 diameter ratio; and even when the range of gases includes monatomic gases so that $n = 1.2$ to 1.67, the corresponding acoustic ratios are 0.2 and 0.13, respectively, which still covers the usual commercial field satisfactorily.

Hodgson's $(P_2/P_1)^{1/n}$ is more nearly exact, is also dimensionally correct, and is based upon true similarity of flow following an isentropic expansion. Hodgson's concise paragraph, showing its derivation, clearly expresses the essence of flow similarity for expansible gases. However, this operator was not followed by the author since the simple acoustic ratio x/n is certainly more convenient and sufficiently accurate for all commercial metering needs.

Following a modified Maclaurin's expansion:
$(P_2/P_1)^{1/n} = (1-x)^{1/n} = 1 - x/n - 0.6\,(n-1)(x/n)^2$ (almost exactly) $= 1 - x/n$
closely enough for practical metering.

The acoustic ratio x/n may be satisfactorily modified as follows, if unusually high precision should be required:

$$1 - (P_2/P_1)^{1/n} = x/n + 0.6\,(n-1)(x/n)^2$$

and this $1 - (P_2/P_1)^{1/n}$ used as a basis as in Figs. 2*b* and 4*b* which show Ruppel's calculated values and the Beitler-Bucher steam data for orifices.

The acoustic ratio must not be used blindly for all types of expansion, since it is based upon the ratio of the velocity of the fluid to that of sound in the fluid, and can hold rigorously only when this ratio properly includes the pertinent variables. The velocity of a sound wave depends upon isentropic compressions and expansions and for the acoustic ratio to be theoretically correct it is necessary for the velocity of the fluid similarly to depend upon isentropic compressions and expansions, as is actually substantially the case with flow through nozzles and orifices with flange or throat taps. For pipe taps which use the loss

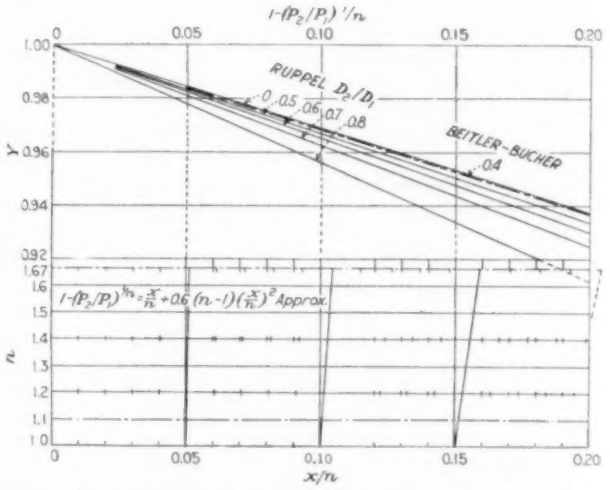

Fig. 2*b* For Throat Taps. Relation Between Expansion Factor Y and $1 - (P_2/P_1)^{1/n}$

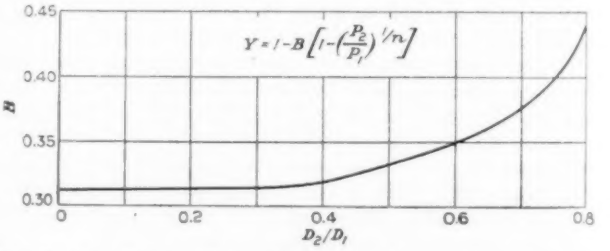

Fig. 4*b* For Throat Taps (Based on $x/n = 0.10$). Relation Between Expansion Constant B and Diameter Ratio D_2/D_1

across the orifice, there is a question as to whether this applies, since this differential is practically isothermal for a perfect gas, being substantially dissipative. For non-isentropic expansions, such as the isothermal, the expansion factor no longer depends strictly upon the acoustic ratio x/n but rather upon the separate ratios x of pressure and n of the specific heats as confirmed by Dr. Edgar Buckingham. However, for the pipe taps the author considers that the acoustic ratio x/n should still be significant and probably adequate since it controls the expansion of, and hence the actual diameter of, the *vena contracta* which, according to Borda's law, chiefly determines the overall loss. The author anticipates that an extension of Ruppel's calculations for this case would be closely checked by experimental data for pipe taps with various gases. Such data would be most welcome.

Much of the author's paper deals with an expansion correction for gaseous fluids. U. S. Bur. of Stds. R. P. 49 on orifices shows that the correction for orifices is small when calculations are based upon the mean pressure $(P_1 + P_2)/2$. Consequently,

[38] "The Laws of Similarity for Orifice and Nozzle Flows," by John L. Hodgson, Trans. A.S.M.E., paper No. FSP-51-42, formula [16], p. 313.

it may be of interest that the author some time ago conceived the idea of having the flow directly produce the proper pressure for use in the hydraulic equation. This entirely eliminates the necessity for any expansion factor in commercial metering (being indeed more accurate than the mean-pressure method above). With orifices, this simply involves the use of an impact-type tube for the pressure, while with venturi tubes the "square-root" pressure tap is taken at a slightly reduced section immediately downstream from the standard throat. For any commercial differentials, the deviation from "square-rootness" with such "square-root" orifices and venturi tubes is less than the experimental error of a tenth or so of one per cent, as determined in recent tests by the author.

The "square-root" gas meter has the important advantage that it can be compensated precisely for various pressures (really densities) since the instrument does not contain an expansion factor (such as Mr. Conlee mentions), which can only be exactly correct at the single pressure for which the meter is graduated, and must necessarily be inexact as the pressure departs therefrom.

P. J. Kiefer, professor of mechanical engineering at the U. S. Navy Postgraduate School, in private correspondence, agrees with the author upon the use of the Reynolds number as follows:

> Relative to the propriety or reliability of the use of the Reynolds number as a parameter, which practice is so vigorously attacked by Spitzglass and Pardoe, I agree with those gentlemen only to the extent that, like any other physical relation, it must be used with reasonable discretion. However, in view of the truly amazing results which have been obtained by means of the dimensional theory and the Reynolds number in correlating the flow of wide varieties of fluids through pipes and in predicting full-scale performance from model tests, I can go no further with them and am wholly in agreement with Smith's use of that number as one of his parameters.

Dr. Edgar Buckingham's oral discussion of similarity and the Reynolds number at the Symposium was appreciated by the author; his corroboration at this time being most helpful, also his generous correspondence with the author did much to eliminate errors and increase the usefulness of this paper.

Prof. R. L. Daugherty's clear remarks at the same time, confirming the use of the Reynolds number with any particular differential producer for a variety of fluids, was welcome as confirmation of the basis proposed by the author.

While Professor Pardoe and Mr. Spitzglass at the Symposium failed to agree completely with the author, he acknowledges the exceptional value of their remarks which have done a great service in forcing clearly worded expressions from the advocates of similarity that will aid immeasurably in assisting the general understanding of the subject.

Mr. Slocum, in his printed discussion, gives the relative velocity criterion for similarity as $V = v\sqrt{L/l}$, which the author has shown to enter where an open surface exists, as with a ship or an open conduit, and not to exist for a flow in a closed conduit of fixed shape. Slocum's remarks on the fundamental difference between flow in a conduit and the passage of a ship through open water agree with the author's paragraph in Appendix 3 under "Physical Description of Flow Phenomena." That eddy-flow similarity exists at identical Reynolds' numbers was early experimentally demonstrated, see Report of Advisory Committee for Aeronautics, 1911–12, p. 97.

Dr. Witte's confirmation of the use of the Reynolds number is invaluable as to the criterion for the similarity with liquids and low differential gas measurement; however, the author has extended the range of similarity into the high-differential régime of gaseous flow by the use of the acoustic ratio as an additional factor. The recent advance in this subject, as set forth in the author's paper, is clearly evidenced by Witte's comment that "for larger expansions (differentials in gas measurement) there is nothing definite that the law of similarity can show about the coefficient and in fact the coefficient is different at larger differentials."

Dr. Jakob's statement as to the work of Odquist and others also confirms the advance in the practical metering of gaseous fluids which the author's paper presents in the simple acoustic ratio.

Mr. Chick's invaluable assistance in the considerable work involved in preparing and checking the author's paper has not been adequately acknowledged. His remarks in the discussion clearly bring out the essential points of the Symposium, especially as regards correcting the erroneous concept of an "absolute" size (pipe diameter) effect, clearly showing it actually to be due to inexact reproduction of geometrical similarity in the various sizes.

Mr. Pigott, as chairman of the Fluid Meters Committee, has been exceptionally generous throughout in his assistance and guidance, which was instrumental in bringing this paper into the shape that would be most useful in the subsequent revision of the Fluid Meter Report—Part One.

J. M. Spitzglass. Mr. Slocum very aptly introduced the general principles of dynamical similarity in his discussion. Furthermore, he has shown that there *are* exceptions to the law of similarity in its general application and that there *are* limitations to be considered also in its particular application to fluid flow in closed conduits.

Dr. Witte, on the other hand, believes that ". . by adhering to the given assumptions one must absolutely demand the same dimensionless coefficient for equal values of Reynolds' function in the case of restricted openings."

Dr. Jakob remarks that ". . there is no doubt about the principle of similarity, but under the circumstances, it is very doubtful whether similarity can be fully applied and taken into consideration."

Mr. Chick insists that ". . in the case of closed conduits . . the Reynolds number is the *only* criterion for complete similarity." He further maintains that the author erroneously gives one to understand that the Reynolds number is not a criterion of similarity in the region of turbulent flow.

The author does not "condemn the validity of such a relationship as the Reynolds number." Its value as a parameter for correlating experimental data is well established. Thus far in the discussion he is the one who pointed out the only known case where dynamical similarity and particularly the Reynolds number applies directly without exception and that is the law of Poiseuille for capillary tube discharges. With all due respect to the Euler-Stokes fundamental equations, one finds that their assumptions do not completely cover the full relationship of dynamical similarity which is exhibited in the law of Poiseuille.

Beyond the region of laminar flow the characteristics of fluid motion become much more complex. When full turbulence is reached the Reynolds number loses its significance in the determination of the coefficient. It is paradoxical to state that the Reynolds number is the *only* criterion for similarity in the region of turbulent flow and at the same time assert that in that region the coefficient remains practically "flat" for all values of the Reynolds number. The fact is that the coefficient is not flat but varies with the size of the pipe. How much this variation is can be determined only by experiment.

HYD-52-8

The Kaplan Adjustable-Blade Turbine

By B. E. SMITH,[1] YORK, PA.

In this paper the author gives details of construction of the Kaplan adjustable-blade hydraulic turbine, and tells of the advantages obtained by adjusting the blades and the wicket gates simultaneously. This turbine differs from the ordinary wicket-gate turbine in the shape of the top plate and the construction of the runner and shaft. The top plate is shaped so as to form a transition space free from vanes between the wicket gates and the runner, in which the direction of flow of the water is changed from radial to axial. The runner hub carries the movable blades, and the operating connections for moving the blades are inside the single-piece hub casting.

THE FIRST known instance of an attempt to use an adjustable-blade turbine is evidenced by the United States Patent No. 67,994, issued to Ludlow in 1867. In this design only the blades were adjustable. There were no water-control gates on the turbine, and stationary guide vanes were used.

About the time the Ludlow patent was granted, there were also many patents issued showing axial-flow runners with adjustable gates of the cylinder, wicket, and other types. Apparently, however, the advantage to be obtained by adjusting the blades and the gates simultaneously to maintain a predetermined relationship was not realized, and no attempt was made to design or build such a turbine. The first application of this principle was made, about 1912, by Dr. Victor Kaplan, of Brünn, Czechoslovakia, who filed patent applications in Europe about 1913 and in the United States in 1914. Dr. Kaplan conceived the ideas and carried on the investigations and tests which led to the development of the modern high-specific-speed propeller-type runner. During these laboratory tests he discovered the marked advantages to be obtained by adjusting the blades and the wicket gates simultaneously. The historical development of the Kaplan turbine is fully set forth in the article written by himself, "Die Entwicklung des Kaplan-Laufrades," in the "Wasserkraft Jahrbuch," 1927–1928, pp. 414–424.

Due to the disturbance in business conditions caused by the war, apparently no attempt was made either in Europe or in this country to make use of the Kaplan designs in a practical way until about 1920. Shortly after this date, a European builder entered into a contract to furnish two turbines with automatically adjustable blades operating under a head of 20 ft. and developing 1100 hp. each. This installation was rapidly followed by others of all capacities and operating under various heads. One European builder alone has furnished 85 turbines of this type, developing a total of 187,490 hp. under heads of from 7 to 48 ft., and in sizes up to 40,000 hp in one unit. During this same period the same manufacturer has built only 19 fixed-blade propeller-type turbines with a total capacity of 79,000 hp. At the present time, European practice is to install turbines with automatically adjustable blades in practically every instance where the head conditions are suitable.

Propeller-type turbines were introduced in the United States about 1917, but it was not until 1923 that the first adjustable-blade turbine was installed in this country. This unit had to be shut down and the flume unwatered in order to make the adjustment of the runner vanes, which were bolted to the runner hub. In 1925 an adjustable-blade turbine was installed with an arrangement whereby the runner vanes could be adjusted from the turbine pit when the unit was shut down, without unwatering the flume. Since that time several units of this type have been installed in this country.

In 1927 an American manufacturer acquired the exclusive rights to the Kaplan United States patents for turbines which permit the automatic simultaneous adjustment of the runner vanes and wicket gates while the unit is in operation. The first automatic adjustable-blade turbine was sold in 1928, and this order was rapidly followed by other contracts. Since that time this company has sold 16 adjustable-blade units operating under heads of from 10 to 40 ft. and developing a total of 37,366 hp. Table 1 gives the details of these installations.

FIG. 1 CONSTRUCTION OF THE SINGLE-PIECE HUB CASTING

The adjustable-blade Kaplan turbine is constructed in the same manner as an ordinary wicket-gate turbine, except for the shape of the top plate and the construction of the runner and the shaft. The top plate is shaped so as to form a vane-free transition space between the wicket gates and the runner, in which the direction of flow of the water is changed from radial to axial. The construction of the runner hub, which carries the movable blades, requires special attention, due to the comparatively small space available. All of the operating connections for moving the blades must be contained inside the single-piece hub casting (see Fig. 1), and must be of such form that they will operate

[1] Secretary, S. Morgan Smith Co. Jun. A.S.M.E. Mr. Smith was graduated from Cornell University in 1239 with the degree of Mechanical Engineer, and was for the next two years associated with the Georgia Railway & Power Co., engaged in the design and field construction of hydroelectric plants. Since 1926 he has been connected with his present concern, engaged in the manufacture of hydraulic turbines.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

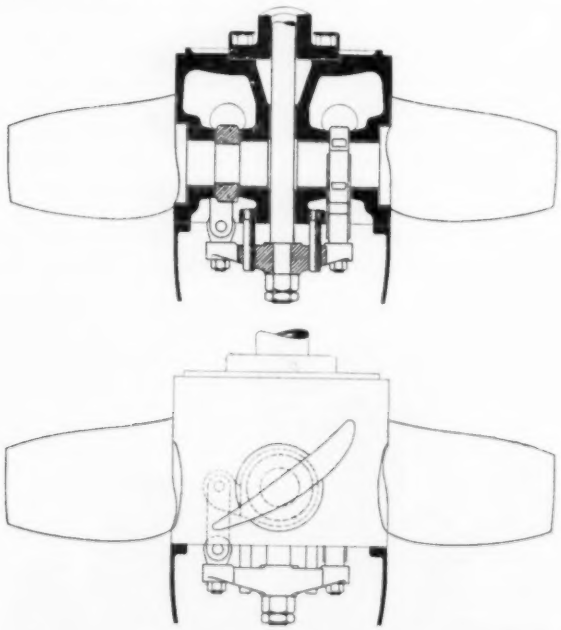

FIG. 2 PRINCIPLE OF OPERATION OF THE KAPLAN ADJUSTABLE-BLADE PROPELLER RUNNER

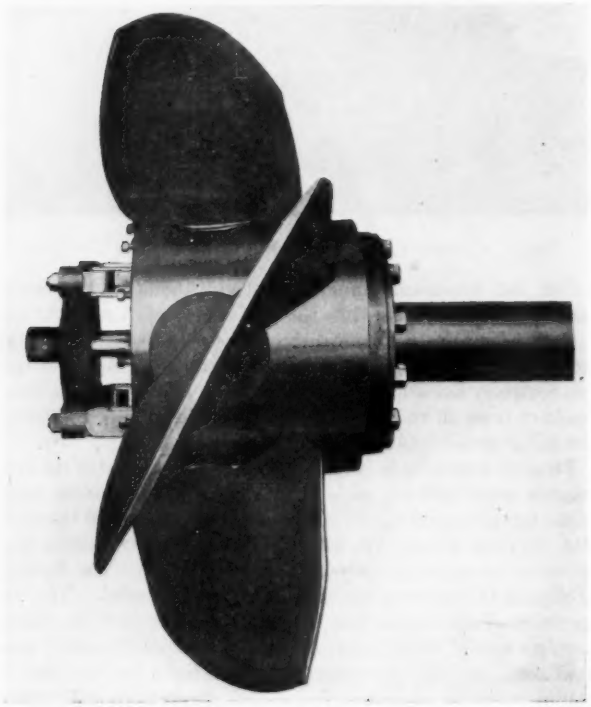

FIG. 3 RUNNER WITH BLADES IN THE OPEN POSITION

indefinitely under the most severe service requirements, without any adjustments. By very carefully utilizing every cubic inch of space, a design has been developed which has proved eminently satisfactory in the many plants already built and in operation. The stresses are held within conservative limits to guarantee freedom from excessive strains and deformation, and to reduce the possibility of wear to the absolute minimum. Careful inspection of the Kaplan turbines already in operation for several years shows no signs of wear.

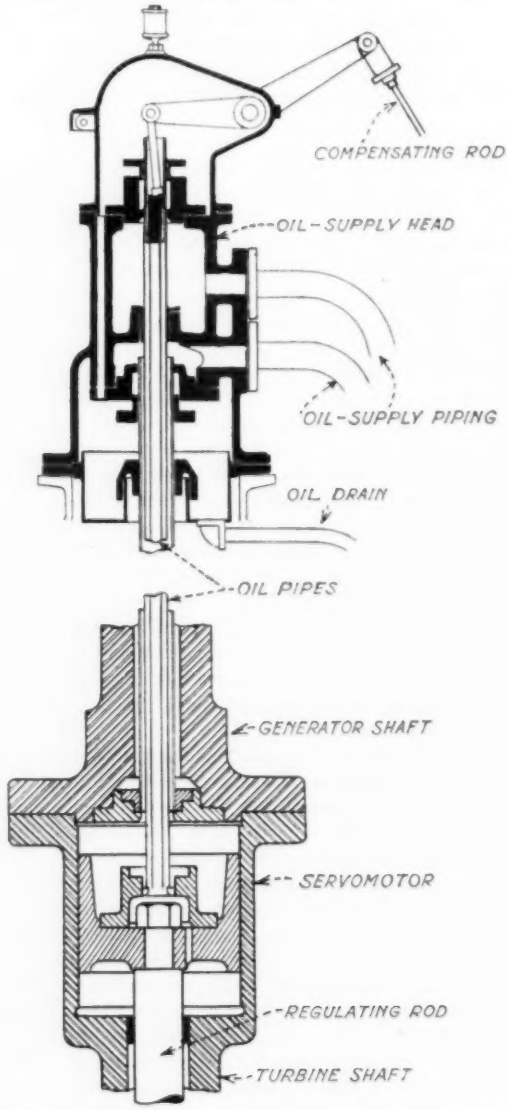

FIG. 4 SECTION THROUGH OIL-SUPPLY HEAD AND THE RUNNER-BLADE SERVOMOTOR

The hub is bored out and bushed with bronze to receive the trunnions of the runner blades. A crank is keyed to each trunnion and clamped to secure the blade against lateral displacement. These cranks, which stand normal to the shaft axis in their mid-position, are connected to a sliding cross by means of links and eyebolts. The cross is carried on a sliding regulating rod which

operates inside the hollow turbine shaft. This regulating rod is guided in bronze bushings and moves axially in the shaft to move the blades through the agency of the sliding cross, the links, and the cranks. The eyebolts and links are bushed with high-grade bronze. The cross slides on keys, which prevents any motion except in an axial direction.

Fig. 1 shows an end view of the Kaplan adjustable-blade runner. Fig. 2 shows a cross-section through the hub of the runner and an outside view of the hub with the lower section removed. Fig. 3 shows a runner with the blades in the open position.

In order to provide constant lubrication for the moving parts in the hub, it is filled with a heavy-bodied oil, which is supplied through the hollow turbine shaft through openings located at a convenient height for refilling. Each runner-blade trunnion is packed against leakage where it goes through the hub body, so that oil loss due to leakage is eliminated. This packing is arranged so that it, in combination with the inside oil pressure (partly static due to the head in the hollow shaft and partly in centrifugal head due to the rotation), prevents the seepage of water and sand or other impurities into the hub. A brass pipe plug is provided in the lower section for draining the oil if necessary.

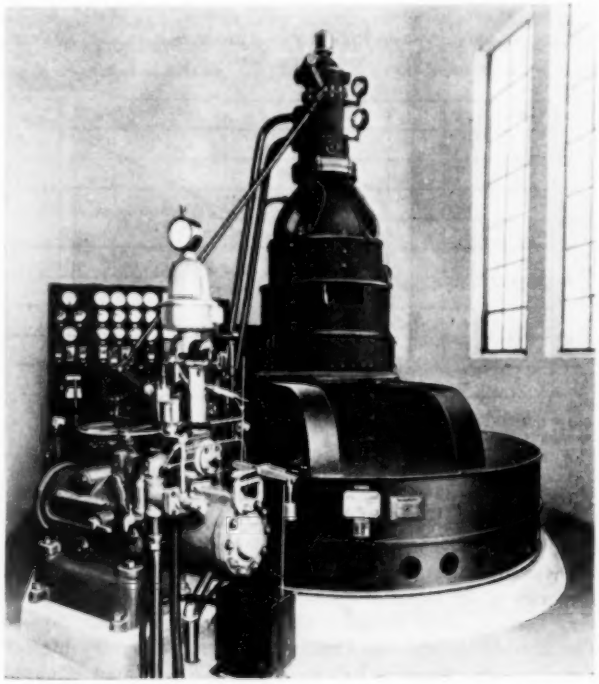

FIG. 5 GENERATOR WITH OIL-SUPPLY HEAD AND OIL PIPING IN PLACE

The runner vanes and hub are made of cast steel. Great care is used to finish the vanes to templets, so that they will have the correct form and offer the least resistance to the flow of water through the turbine.

The regulating rod in the hollow turbine shaft is moved axially by a servomotor arranged between the flanges of the turbine and generator shafts. The piston is connected directly to the upper end of the regulating rod. The servomotor is operated by oil supplied under pressure from above, through two pipes arranged concentrically within the hollow generator shaft. The inner pipe carries oil to the lower side of the piston and is rigidly connected to it, moving up and down with the piston. The governor-compensating mechanism is connected to the upper end of this pipe. The two pipes to the servomotor terminate in two distributing chambers arranged one on top of the other, and mounted on the upper end of the generator shaft. Special provision is made to prevent any leakage of oil over the generator. Fig. 4 shows a section through the oil-supply head and the runner-blade servomotor, and Fig. 5 shows a generator with the oil-supply head and oil piping in place.

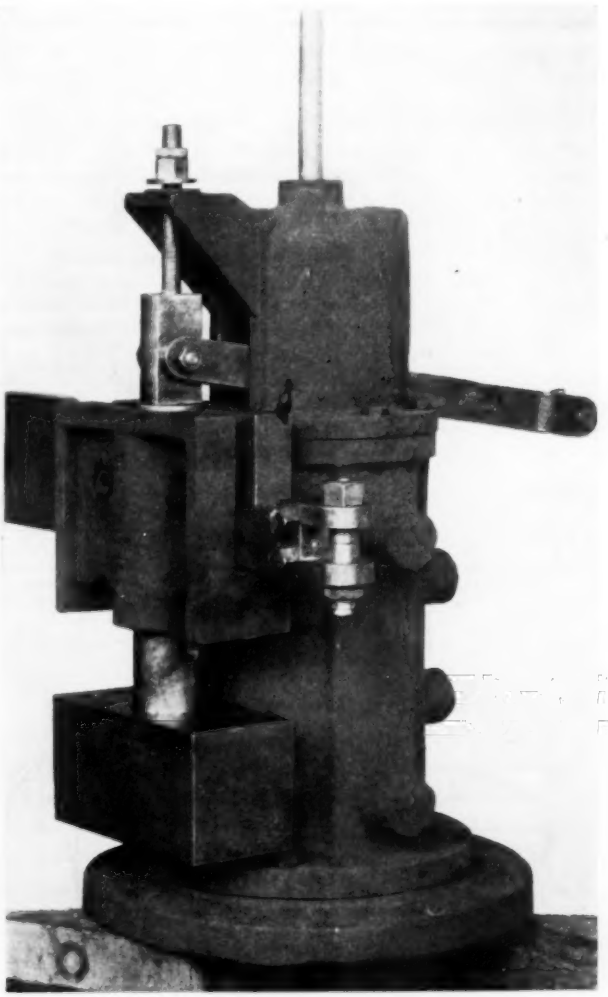

FIG. 6 DISTRIBUTING VALVE AND CAM

The governor itself is a simple speed governor, which operates the wicket gates in the usual manner, either through a vertical gate shaft or through servomotors and push-and-pull rods connected to the turbine-gate shifting ring. In addition, this governor has a second distributing valve controlling the flow of oil to the runner-vane servomotor in the turbine shaft. A cam is connected to the gate-operating mechanism and to the runner-blade compensating connections in such a way that the gates and runner blades always move in the definite relationship required to give the maximum efficiency for every variation in load. Fig. 6 shows this distributing valve with the cam in place.

The simultaneous adjusting of the runner blades and wicket gates maintains the best conditions of flow through the turbine throughout the entire range of output, thus giving exceptionally high part-load efficiencies and consequently very flat efficiency-horsepower curves. Since the blade and gate angles and openings always have the correct relationship to each other, the automatic

adjustable-blade turbine always operates with maximum smoothness, and with minimum vibration and pitting.

Fig. 7 shows a comparison of the efficiency-load curves of a Kaplan automatic adjustable-blade turbine with those of fixed-blade turbines at various heads and with different runner-blade angles. The dotted curves show the performance of a fixed-blade runner at various heads, and the dash-and-dot lines show the results obtained at 26 ft. head when three different fixed-blade runners are used, one in which the blades are inclined at

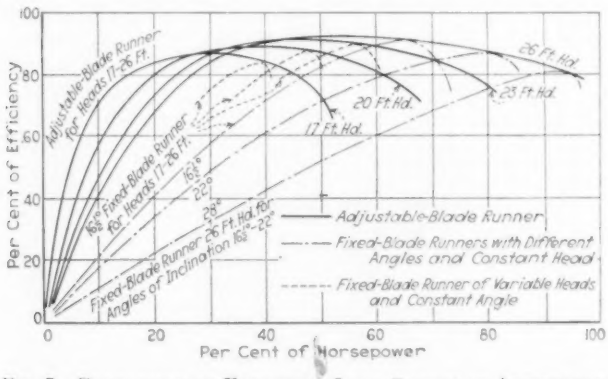

Fig. 7 Comparison of Efficiency-Load Curves of Adjustable-Blade With Fixed-Blade Turbine

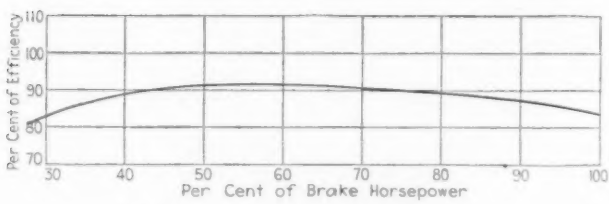

Fig. 8 Typical Efficiency-Load Curve

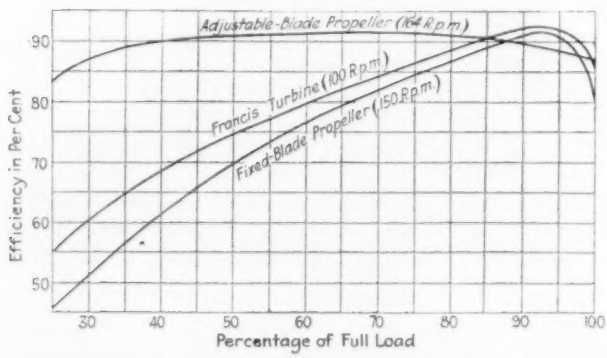

Fig. 9 Comparisons of Efficiencies of Adjustable Blade, Fixed Blade, and Francis Turbines

28 deg., another at 22 deg., and the third at 16½ deg. An infinite number of curves of fixed-blade runners with different blade angles will develop the envelope curve shown by the full line for 26 ft. head. Automatic adjustment of the blades and gates maintains the correct relationship between them to secure the highest efficiency for each blade position. Four such envelope curves have been drawn, using full lines, showing the horsepower and efficiency of an automatic adjustable-blade turbine under heads of 17, 20, 23, and 26 ft. These curves show how the adjustment of the blades holds the efficiency of the turbine up to the maximum which could theoretically be obtained by using a different fixed-blade runner for each special condition of load and head.

A study of this figure and a consideration of the operating features involved clearly show that, as a practical matter, it is impossible to obtain even an approximation of the envelope curves with a hand-operated adjustable-blade runner requiring a shutdown for each adjustment. In addition to the necessarily uneconomical operation of the non-automatic turbine, there is involved a substantial amount of increased physical labor and attendance, and also loss of power during the periods of shutdown required to adjust the blades when variations in load or head occur.

Fig. 8 shows a typical efficiency-load curve of a Kaplan automatic adjustable-blade turbine with a specific speed of 161. The curve is very flat, with more than 85 per cent efficiency from 33 to 96 per cent load and more than 90 per cent efficiency from 43 to 75 per cent load.

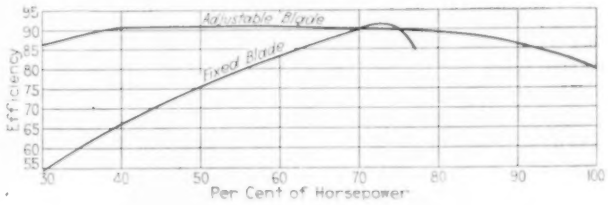

Fig. 10 Comparison of Fixed- and Adjustable-Blade Turbines of Same Size

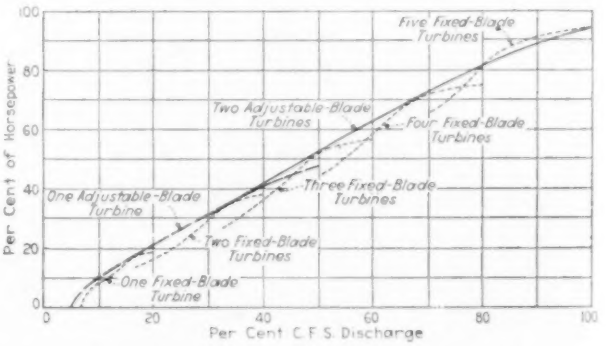

Fig. 11 Comparison of Load and Discharge Curves of Adjustable- and Fixed-Blade Turbines

Fig. 9 shows a comparison of a Kaplan automatic adjustable-blade turbine and a fixed-blade turbine with a high-specific-speed Francis turbine. This figure shows the marked advantage in efficiency of the adjustable-blade turbine at all loads except in a very narrow range at about 90 per cent of full-load capacity. The fixed-blade and the Francis turbines attain very high efficiencies only at nearly full load, and the part-load efficiencies drop off very sharply. Also, for the same full-load capacity, a smaller adjustable-blade turbine can be used, and consequently it can be operated at a higher speed, thus permitting the use of a smaller and cheaper generator. The higher the specific speed for the fixed-blade and the Francis turbine, the faster the efficiency drops at part load. Therefore, with high specific speeds the efficiency of these turbines attains satisfactory values only within a small range of regulation. Consequently such turbines can be considered only where they will be operated with loads varying over only a small range at near full capacity.

The Kaplan adjustable-blade turbine has a considerably larger capacity than a fixed-blade turbine of the same size and speed. Fig. 10 illustrates this difference very clearly. This feature permits the automatic adjustable-blade turbine to be designed and selected to provide a liberal overload capacity. The turbine is very flexible in this respect, and the excess horsepower for peak

loads or for low-head flood conditions can be provided without affecting the normal head economy, and usually with little or no reduction in efficiency at small gate openings.

Fig. 11 shows the possibility of reducing the number of units in a power house without reducing the total capacity, by using adjustable-blade instead of fixed-blade runners. This curve shows that two automatic adjustable-blade units could be substituted for five smaller fixed-blade turbines, and the efficiency at any discharge would be higher than if fixed-blade units were used. The use of the two adjustable-blade units results in material reductions in the cost of the mechanical and electrical equipment, and also reduces the size and consequently the cost of the excavation and of the power house itself.

The adjustable-blade turbine is particularly suited for developments where the quantity of water varies greatly. On account of the high part-load efficiencies, these turbines deliver much more power than fixed-blade axial-flow or Francis-type turbines in times of low water. Thus the total annual kilowatt-hour output available is greatly increased. The realized increase is greater than the computed gain, as in actual plant operation the Francis units are not started and stopped in accordance with the individual efficiency curves.

Fixed-blade axial-flow turbines, on account of their narrow operating range at high efficiency, can be considered only in comparison with adjustable-blade turbines when they can be constantly operated at nearly full load. This condition applies only where such machines are used to carry base load and are tied in electrically with a large system so that other units may be used for regulating purposes. Where there is a large quantity of water to be handled, a number of fixed-blade turbines may be installed and only as many units operated as the immediate quantity of water justifies. Even in this case the total yearly output can be increased by using one or more automatic adjustable-blade turbines for regulating purposes.

As a class, Kaplan turbines are essentially low- and medium-head machines; however, the head under which they may be used is constantly increasing and heads up to 66 ft. may now be developed with perfect safety.

Adjustable-blade turbines are placed in settings similar to fixed-blade axial-flow or Francis-type turbines; however, with these machines the allowable draft head decreases with increasing head and increasing specific speed. Consequently this feature must be carefully considered in designing the setting, or uneven operation and also pitting may result in the turbine. The design of draft tube also affects the operation of this runner. It has been found that the elbow-type draft tube is best suited for all units except small ones where the cost of excavation permits the use of a straight conical tube. A properly designed elbow-type draft tube reduces excavation to a minimum, provides maximum support for the superstructure, simplifies and cheapens the form work, has no underhanging parts requiring expensive reinforcing, and enables the turbine to develop maximum efficiency.

Progress in the Iron and Steel Industry in 1929

Contributed by the Iron and Steel Division

Executive Committee: C. Snelling Robinson, *Chairman*, F. C. Biggert, Jr., Walter Trinks, and W. W. Macon

TECHNICAL progress in the iron and steel industry in 1929 has been rather unusual, and there is every indication that much greater advances will be made from time to time because of the intensive study that is being prosecuted in our research laboratories and the practical application of the results thus obtained. In order for steel companies to keep in a fairly competitive position it is necessary to make a determined effort to utilize all of the technical developments possible. This is no time to be satisfied with present processes, nor to take the attitude that there is no further improvement to be made.

While, in general, the selling prices of materials have not greatly increased, earnings have been much better owing to economies which have been effected in the course of production and to the careful attention given to methods used. Much of the decrease in the cost of production has been brought about by large investment in new machinery and plant facilities. The output of steel products has increased greatly, largely due to the same causes rather than to the building of new mills.

The tendency toward mergers with a view to decrease in over head and to general economies of production has been evident in the iron and steel industry as well. Among the important moves of this kind may be mentioned the following. For the first time in many years the U. S. Steel Corporation has absorbed an existing steel mill by taking over the Columbia Steel Company with plants at Pittsburgh, Calif., and elsewhere on the Pacific Coast, apparently in an effort to provide that growing region with locally made material. A merger of the A. M. Hanna properties, the Weirton Steel Company at Weirton, W. Va., and the Great Lakes Steel Corporation with a plant under construction in the Detroit region, has resulted in the formation of the National Steel Company. The Central Alloy Steel Company, formed some two years ago through a merger of the Central Steel Company, of Massillon, Ohio, and the United Alloy Steel Company, of Canton, Ohio, has absorbed the Interstate Iron and Steel Company in Chicago, which makes it one of the most important alloy-steel producers in the country. The control of the Donner Steel Company has passed to Cleveland interests headed by C. S. Eaton, and this has been followed by an amalgamation of the Donner Steel Company with the Witherow Steel Company. The Republic Iron and Steel Company first acquired the Steel Tubes Company, which gave it control of important patents for the manufacture of electrically welded pipe, for which purpose a new plant has been erected at Warren, Ohio. This was followed by the acquisition of the properties of the Union Drawn Steel Company, in Massillon, Ohio, Beaver Falls, Pa., and elsewhere. The papers have repeatedly announced that a tremendous merger was under way involving, according to some, the Republic, Youngstown, and Inland companies, while others included with these the Otis Steel, Midland Steel Products, and even the Bethlehem Steel Company. No evidence is available to show that any such undertaking is actually being pushed. In the tool-steel field, likewise the Ludlum Steel Company has absorbed the Atlas Steel Corporation of Dunkirk, N. Y., with a subsidiary in Canada. This makes it one of the largest units in its field in this country.

Of late considerable attention has been called to the Detroit district and to the large development which is taking place in that section.

Most of the nine months of 1929 were record-breaking ones in nearly all departments of the steel industry. The production of pig iron during that period totaled 32,649,182 gross tons, or an average per month of 3,627,687 gross tons, which means that were this rate to keep up for the remainder of the year the total would run well over 40,000,000 tons, compared with 37,800,000 in 1928 and 39,100,000 in 1926, a record year. The average production for the first nine months was about 85 per cent of capacity as computed by the American Iron and Steel Institute.

The nine months' production of steel ingots totaled 43,243,404 gross tons, which is also a record tonnage for a like period, and the average per month for the nine months was 4,804,822 gross tons. The production average was about 92 per cent, based on the capacity computed by the American Iron and Steel Institute.

Iron Ore—Coal and Coke

There is little doubt that 1929 will set a new high record for ore shipments from the Lake Superior region. Shipments to October 1 totaled 53,264,927 gross tons, with shipments during the months of June, July, and August being over 10,000,000 tons per month. At this record-breaking rate it is expected that 1929 shipments will exceed 67,000,000 tons as against the record set in 1916, of 66,000,000 tons.

There has been a tremendous development of interest in ores during the past year: more exercising of options on both high- and low-grade ore properties, particularly during the last few months, than there has been in many years. There has been more interest in concentration of ores in the last year than for many years; and there is an increasing appreciation of the vital necessity of ore reserve; and, because of these factors the ore situation is becoming more firm at home and abroad, and beneficiation of the low-grade ores will gradually assume greater importance in production.

In the field of individual developments the following, among others, may be pointed out.

The last year has seen earnest steps taken and numerous plants built to beneficiate our coals. Both wet and dry processes are in operation commercially, but it perhaps is too early to draw definite conclusions as to the best one to use. In fact, there is such a variation in individual coals and the purposes for which they are used that no one process may fit all cases.

When coal has been improved and is of a quality suitable for metallurgical coke, it certainly tends to greater uniformity in the coke.

The coke used for metallurgical purposes has also been greatly improved because of more careful selection of the coals used in making it, and because of proper sizing and screening and the development of a market for the remainder of the product.

Blast Furnaces—Open-Hearth Furnaces

Recent experience seems to have clearly indicated the merits of the wide-hearth blast furnace. One such furnace with a hearth diameter of 24 ft. 6 in. and a bosh of 26 ft. 3 in. is said to have produced in 1928 a daily average output of 1008 tons.

A paper entitled "Recent Developments in Blast-Furnace

Construction and Practice" which was presented at the Society's Cleveland meeting by Arthur G. McKee, covers quite thoroughly the more recent advances in iron making. In it the author discusses construction, size, auxiliaries, hot-blast stoves, gas-cleaning equipment, and the use of blast-furnace gas in other departments of a steel plant. He also pays a greatly deserved compliment to the group of enthusiastic engineers in the Bureau of Mines at its Minneapolis headquarters. The investigations already made there have been of great value, and the watchful cooperation of all interested in the manufacture of iron and steel should be unstintedly given.

Blast-furnace gas is now being used satisfactorily at coke ovens, thereby releasing the coke-oven gas for other purposes. Mixtures of these gases have been found to give excellent results in other heating operations, and with reduced costs.

The more economical utilization of blast-furnace gas in conjunction with powdered coal in the generation of high-pressure steam is important.

Recent developments in blast-furnace design have called for corresponding changes in turbo-blowers, charging and filling equipment, control of charging, heat practice, and more effective stove equipment.

Proper sizing and preparation of coke and other raw materials and sintering of ores and flue dust have done much to make a more uniform and increased product, and increasing knowledge of the advantages of sintering has resulted in an extensive program of sintering-plant building, these plants apparently being largely of the Dwight-Lloyd type.

No definite decision has been reached as to the maximum size of open-hearth furnaces. According to King and others, the large furnaces are the most economical, and their control is satisfactory.

Doubtless what might be most economical for low- and medium-carbon steels where large tonnages could regularly be disposed of, might not prove to be so for other steels calling for great variation in analysis and which are of limited application in use.

Size might well be a plant problem.

The extended use of new designs of ingot molds and hot tops is of interest.

The Metallurgical Section of the Pittsburgh Experiment Station of the U. S. Bureau of Mines in cooperation with Carnegie Institute of Technology and the Metallurgical Advisory Board has conducted experiments, the results of which have recently been released, showing that the amount of iron oxide dissolved in liquid steel is very much higher than formerly believed to be the case. This fact, it is stated, "changes the concept of methods of working open-hearth heats to a considerable extent, in that it emphasizes the importance of chemical composition and physical properties of the slag and the necessity for an even more careful study of deoxidizers than has been made up to the present time."

Experiments on electrolytic methods for the extraction of nonmetallic inclusions from steel are also under way.

A paper was read before the Iron and Steel Institute by E. J. Janetsky entitled "A Study of Basic Open-Hearth Slags by Solidification Tests." Therefore there are good reasons to hope for real enlightenment on open-hearth practice.

The Bessemer Process

Under the leadership of Dr. G. B. Waterhouse the industry can confidently look forward to practical suggestions for improvements in practice in the bessemer process. Already changes in operation and certain refinements have brought about the replacement of open-hearth with bessemer steel in certain lines.

Rolling Mills

Work has been going on looking to the improvement of the newer methods of rolling wide strips by the continuous process and getting the product of proper quality and under control.

Advances have been made to a marked degree on older mills of the ordinary pattern in output and cost, largely due to continuous heating and rolling changes.

Electrification of old mills and installation of new ones have continued throughout the year. One of the newest is a Morgan mill built for the Sharon Steel Hoop Company, which rolls strip from $2^1/_2$ in. to 10 in. wide at speeds up to 2400 ft. per min. in coils of from 150 lb. to as high as 2000 lb. All strips are produced from 30-ft. billets. The mill is so arranged that the pulpit operator can receive instructions as to operations and speed changes from a loud speaker mounted on the pulpit, the roller talking into a microphone located on the operating floor.

Pipe

Many improvements have been made in the methods of production and subsequent treatment of seamless tubing, and expanding up to large sizes has been introduced commercially. New methods of welding have come to the front and a huge tonnage of the larger sizes has been manufactured; smaller sizes and light gages are also being produced on a large scale.

Wrought Iron

Wrought iron is being commercially produced at Warren, Ohio, by the Aston process, in which a blown metal is pounded into molten slag of the proper analysis held at the right temperature, the resulting sponge or ball of iron being then squeezed, after the slag has been poured off, and the bloom rolled without reheating into muck bar or billets.

Alloy Steels

Great progress has been made in the development of steels for special purposes, such as those which will resist corrosion and are capable of withstanding high temperatures, and also in the ability to produce a large output at decreased costs.

Furnaces

Marked improvements have been made in heating, etc. Kathner and other normalizing furnaces have been installed and are producing a satisfactory product of sheets. The Kathner furnaces use insulated shafts throughout as the conveying mechanism to avoid loss of heat. They are 155 ft. long, and have a heat zone of 75 ft, and a cooling zone of 80 ft. The heating zone is divided into a preheating section of about 35 ft. and a soaking section of 40 ft. The preheating section has no burners within 15 ft. of the entering door, and receives its heat by the backflow of gases from the rest of the furnace. Automatic control equipment has been a factor of importance in this development.

The size of arc furnaces has been steadily growing, the largest, it is believed, being operated by the Timken Steel and Tube Co. at Canton, Ohio. These furnaces in their rating closely approach to the smaller size of the regular open hearth. Of late the electric furnace has found an important application in the field of recovery of chromium- and nickel-steel scrap. When handled in an ordinary open hearth this scrap loses the valuable alloying elements to the slag. In an electric furnace it can be melted practically without any such loss. The furnace installed for this purpose is said to be an induction furnace with the coils located above the hearth. It is of 6 tons rated capacity, and while its initial cost is rather high owing to the very low frequency that has to be used, the economic results of operation are said to have proved to be highly attractive.

The high-frequency furnace has been making further progress, unusually large units having been installed in several places, among others, at the Heppenstall Forge and Steel Company.

An interesting feature of the development of this furnace is the continuous reduction in the frequency employed, which makes for cheaper generators and controlling machinery.

Nitriding

This process was developed in Germany some five years ago. Only during the last year has an apparently successful effort been made to introduce it on a commercial scale in the United States. The largest nitriding furnace in the world is being installed in a plant of a midwestern steel company.

Machines and Tool Materials

Wonderful strides have been made in the last two years in machine-tool design. In fact, so many improvements have been made as to render practically obsolete, for purposes now required in up-to-date shop practice, tools but a few years old.

The newer cutting materials have demanded some of these changes. A whole series of materials of great hardness and resistance to wear has been brought out. Among these are Carboloy, Firthite, or Widia, a tungsten carbide embedded in a matrix, the essential constituent of which is cobalt. Others include such materials as Stoodite (a hard chromium-iron alloy with some manganese), Borium (tungsten carbide base), and Blackor (also a tungsten carbide alloy). All of these are either welded on or mechanically attached to a steel extension piece, while some, including Stellite, may also be applied as a facing on a steel base.

Sponge Iron

Blast furnaces have not as yet been eliminated. Rumors are to the effect that headway is being made with the so-called Hornsey process. The Smith process may prove to have a certain field; some of the results look hopeful.

Centrifugal Casting

Maj.-Gen. C. C. Williams has announced that experimental work on the centrifugal casting of guns leads to the belief that the process has been satisfactorily established for the 37-mm. gun, the 75-mm. infantry mortar, and the 75-mm. howitzer. Also that a larger machine is being constructed for production of the 75-mm. field gun and the 105-mm. howitzer. It is asserted that the physical properties obtained from centrifugal castings, after treatment, are superior to those obtained from forgings of the same composition.

Billet Chipping

An earnest effort is being made to do away with the chipping of billets by compressed-air-operated chisels. In the past year several machines have been placed on the market, one of them a miller, another a planer, while a third, for round billets, operates somewhat like a pencil sharpener. A certain amount of research has been done by several steel companies to determine the extent of surface defects which have to be removed by chipping and whether there is any way of reducing their number or eliminating them completely.

Scrap

A research bureau has been launched by the newly formed Institute of Scrap Iron and Steel, Inc., to make a thorough survey of every phase of direct dealing between consumers and producers of scrap. Owing to the wide distribution and use of alloy steels, the proper classification and economical use of scrap steel is becoming of increasing importance.

Foreign Patents

A significant development in the past year is represented by the tendency of American manufacturers to take out licenses under patents originating in Germany. Two of the most important of such developments have been the introduction of cutting metals of the tungsten carbide type, referred to elsewhere, and the introduction of the nitriding process, both inventions of members of the staff of the Krupp Company. Another foreign invention taken up by an American manufacturer is pearlitic cast iron. The Midvale Company, on the other hand, has taken out licenses under French patents owned by the Commentry-Fourchambault et Decazeville Co. for the manufacture of a heat-resisting alloy of the chrome-nickel-iron type.

C. Snelling Robinson, *Chairman.*

Use of Alloy Steels in Iron- and Steel-Mill Equipment

By E. R. JOHNSON[1] and O. BAMBERGER,[2] CANTON, OHIO

Substituting alloy steels for the ordinary carbon steels in its mill equipment is the practice of the Central Alloy Steel Corporation when occasion arises to make a change. Elimination of breakdowns and costly repairs is claimed to be furthered by certain uses of the alloys. A gradual building up of the alloy-steel equipment is taking place. Producing alloy steel itself, the initial cost is low. There are three requirements which permit the substitution of alloy steels: (1) Increase of the physical properties of strength, ductility, and toughness. (2) The ability to withstand wear and abrasion. (3) Resistance to corrosion.

THE steel mill, as well as any other industry, is always aiming to develop a maximum production at a minimum expense. To attain this condition steel-mill equipment must necessarily function with few breakdowns and costly repairs. It is therefore of prime importance that this equipment be designed to operate continuously, for a number of departments in a steel mill operate day and night for the seven days of the week.

To meet this demand it has been found necessary to substitute other materials for the ordinary carbon steels. Our company has been producing alloy steels for many years, and it is therefore only natural that parts are replaced with the various alloy steels. Because of this the initial steel cost of alloy is favorable, and occasionally we can use heats off in analysis for certain classes of work.

In general it can be stated that there are three requirements which permit the substitution of alloy steels for the plain carbon steels:

1 Increasing physical properties with respect to strength, ductility, and toughness. The physical properties that can be obtained depend upon carbon content, alloy content, and resultant heat-treating operations. A comparison of any of the standard physical-property charts brings out the superiority, especially in the larger sections, of alloy steels over carbon steels at similar hardness values. Therefore when weight becomes a factor, it becomes possible to decrease sectional areas by using alloy steels and still have the proper physical qualities.

2 The ability to withstand wear and abrasion. Usually this quality is dependent upon hardness values. High hardness values give the best wearing quality. There are a number of applications where abrasion resistance and toughness are desired. This always is best obtained with alloy steels. Likewise high hardness values with depth of penetration to support surface loading are more easily obtainable by using alloys.

3 Resistance to corrosion, both wet and dry. The latter may be considered scaling at elevated temperatures. Both of these require special alloy materials, with high percentage of alloying content.

To meet these special functions, various alloy steels have been developed by adding additional elements—nickel, chromium, molybdenum, vanadium, tungsten, and copper, either singly or in combination. Nickel steels are used primarily for increased ductility and resistance to shock; chromium steels for resistance to wear at high hardness, along with depth of hardness penetration; molybdenum is generally used in combination with chromium and nickel, bringing out increased physical qualities; while vanadium is used either alone or in combination with chromium. The latter element has a refining influence in grain size and fracture grain size. Tungsten is of course majorly used for high-speed steels. At present the chief function of copper is increasing the resistance of low-carbon materials to weather corrosion.

Heat Treatment

The best qualities of alloy steels are usually enhanced by suitable heat-treating operations. In fact, for certain parts it is necessary to heat-treat. To take care of our parts equipment, we have developed an entirely separate heat-treating unit which includes all facilities for proper treating and handling. This enables one heat-treating unit to concentrate on mill equipment and thus develop a crew of men who understand the various applications and strive to develop the maximum service for each part.

Steel-Mill Equipment

To facilitate the description of the alloy-steel equipment, a large steel mill may be divided conveniently into a number of operations. To begin with, there are coke ovens, followed by blast furnaces, open hearths, pouring and stripping of ingots, soaking pits, blooming mills, chipping beds, finishing mills, sheet mills, strip mills, and a group of miscellaneous departments which include the heat-treat, cold-draw, machine-shop, and fabricating departments. A number of parts equipment, such as cranes, are general to many departments.

At the coke ovens there was a failure of the pushrod on the pusher within three months after receiving the machine. A pushrod was substituted which had been machined from a carbon-vanadium steel of 0.45 to 0.55 C, 0.40 to 0.70 Mn, and 0.15 V. This rod was normalized at 1600 deg. fahr. and reheated to from 1150 to 1200 deg. fahr. The service has now been continuous for 18 months without any indication of failure.

At present the pusher is equipped with alloy-steel track wheels, gears, pinions, and shafting. The track wheels are forged from a chrome-nickel molybdenum steel having an analysis of approximately 0.45 to 0.55 C, 0.50 to 0.80 Mn, 1.50 to 2.00 Ni, 0.70 to 0.90 Cr, and 0.10 to 0.20 Mo. After forging, the track wheels are cooled carefully to prevent the formation of internal ruptures. An annealing treatment is required to make the steel suitable for machining. The heat treatment applied to these wheels is an oil quench of from 1525 to 1550 deg. fahr., followed

[1,2] Central Alloy Steel Corporation. Mr. Johnson was graduated from the University of Michigan in 1921 and obtained a master of science degree in chemical engineering in 1922. He has been connected with the Central Alloy District of the Republic Steel Corporation for the past eight years in various capacities. At present he is acting as assistant chief metallurgist of the Central Alloy District. Mr. Bamberger has been in the employ of the Central Alloy District, Republic Steel Corporation, for the past ten years. He has had extended experience in the heat-treatment of steel for steel-mill equipment and at present has complete charge of this phase of mill work, including the forge shop at the Canton Works.

Presented at the National Iron and Steel Meeting, September 11 to 13, 1929, Cleveland, Ohio.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

by a draw of from 750 to 800 deg. fahr., which gives a hardness of 70 to 75 scleroscope. All the cranes and buggies have been equipped with this type of track wheel. The steel has the property of hardening deeply for resistance to wear and has in addition an inherent toughness to withstand sudden shocks. Previous experience on one particular stretch of track has shown that carbon-steel wheels lasted three months, alloy castings six to eight months, and the foregoing type of track wheel two years, or eight times the life of carbon-steel wheels. In addition there is a saving of numerous installation costs. An illustration of a typical track wheel is shown in Fig. 1.

The gears are made of cast alloy steel having an analysis of 0.35 to 0.45 C, 0.50 to 1.00 Ni, and 0.35 to 0.45 Mo. The gears are annealed, machined, and treated by oil quenching from 1500 to 1525 deg. fahr. and drawn at 900 to 950 deg. fahr., which gives a scleroscope hardness range of 60 to 70 according to size. The use of nickel increases the resistance to impact and at the same time develops sufficient hardness for good wearing qualities. The average life of this type of gear casting is one year to two and one-half years, whereas with plain carbon-steel castings the average life was only three to eight months.

Another part which was changed to alloy steel was the shafting. Generally cold-rolled carbon-steel shafting is supplied with the machines. For shafting we have standardized on a chrome-nickel steel, S.A.E. 3140, which can be oil quenched and drawn to a hardness of 269 to 302. At this hardness the shafts can be machined and yet have 20 per cent greater strength values. This increase in physical properties brought out by heat treating enables one to reduce sectional sizes. Sections under 6 in. diameter are heat-treated; over this diameter the shafts are normalized and drawn.

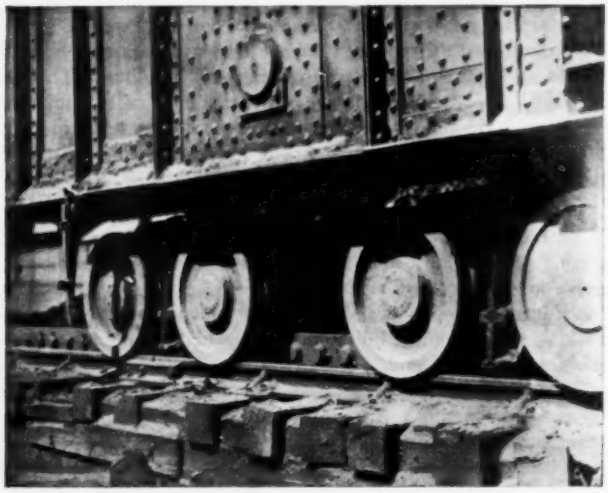

FIG. 1 ALLOY TRACK WHEELS ON ORE-BRIDGE CRANE

Another place for the alloy steel on the pusher, and for that matter on all cranes, is for the pinion gears. For this part fairly high hardness values are required to combat wearing and abrasion. In addition, toughness is essential to withstand sudden load applications. A change therefore has been made to a heat-treated chrome S.A.E. 5150 or chrome-vanadium steel S.A.E. 6150. The hardness value is held within the range of 418 to 477 Brinell.

The foregoing types of steel have been standardized and are used for the particular parts on all cranes in our plant. Armature shafting is also heat-treated S.A.E. 3140 steel.

Along with the substitution of alloy steels for the carbon steel, it is quite essential that design of parts be made to give maximum service life. The various gears and shafting are usually keyed, and it is advantageous to have radius instead of any sharp corners, for it has been found that sharp corners concentrate stress and lead to early failure by fatigue or fracture. Likewise teeth on all gears should be cut to allow a radius at the root of teeth. Fig. 2 presents a view of various alloy-steel gears and pinions.

At the blast furnace stainless-steel tubes have been installed in the power house for soot blowing in the boilers. The type of tubing used previously developed a grain growth and ultimately cracked where the bushings are inserted, thus permitting them to fall out. The present installation of stainless tubes has worked satisfactorily for one year and there is no indication of any failure.

FIG. 2 VIEW OF ALLOY GEAR CASTINGS AND FORGED PINION GEARS

For the automatic stokers there are being used chrome-steel (5150) rollers and chrome-vanadium (6145) shafts. Both of these parts are heat treated to 600 and 550 Brinell, respectively. At this high hardness wear is at a minimum, and due to the great depth of hardness obtainable with these steels, the penetration of wear will be very slow.

After the installation of this power house and the blast furnace, it was found necessary to substitute alloy steels, as a number of parts failed within a short time. On one of the booster pumps the carbon-steel shaft fractured, and it was replaced with a heat-treated S.A.E. 3145 steel at a hardness of 286 to 302 Brinell. The bell rod at the top of the blast furnace was also changed to a heat-treated chrome-nickel steel, for a break of this rod would mean a costly delay.

At the open-hearth furnaces the charging crane has been equipped with various alloy-steel shafts, gears, pinions, and track wheels.

In addition the peel of the crane has been changed to a carbon-vanadium steel (0.45 to 0.55 C, 0.50 to 0.80 Mn, 0.15 V). Due to the sectional size the peel is normalized and then drawn to a hardness of approximately 187 to 207 Brinell. A tensile strength of 90,000 to 100,000 lb. per sq. in. will be obtained.

The dampers on the furnace are equipped with chrome-nickel S.A.E. 3140 connecting rods.

The ladle cranes have the same general alloy-steel parts that other cranes have. The gears are heat-treated to slightly lower hardness values, to minimize danger of fracture or breaks from sudden shocks.

At the blooming mill there are being used adamite rolls, which are high-alloy castings. The alloy content permits much longer life from the standpoint of wear. The table rolls adjacent to the mill on both sides are made of carbon-vanadium steel and have re-

ceived a normalizing treatment followed by a high draw. Carbon steel castings had been used previously, and the constant bumping of the ingots on these table rolls after coming through the mill would break the table rolls. Changing to an alloy-steel forging, the brittleness was eliminated, a table roll was obtained with a tensile strength of 90,000 to 100,000 lb. per sq. in., elongation 20 to 24 per cent, and reduction of area of 40 to 48 per cent. The gears driving these rolls are made from nickel-molybdenum castings and heat-treated to from 400 to 444 Brinell. A carbon-vanadium steel is also used for the spindles which drive the blooming-mill rolls. The fracture of a carbon-steel spindle is shown in Fig. 3.

To take up shocks and excessive loads on the blooming mill, a Falk coupling has been installed. A picture of this is shown in Fig. 4. The springs are made of chrome-vanadium steel, S.A.E.

FIG. 3 VIEW OF BLOOMING-MILL SPINDLE WHICH FRACTURED

6150, heat-treated to from 418 to 444 Brinell hardness. This coupling has enabled increased production and has eliminated the breakage of bolts that constantly occurred in the old type of coupling.

At the blooming mill shears, as well as on all finishing mill shears, we are using either chrome S.A.E. 5155 or chrome-vanadium S.A.E. 6155 steel for shear blades. For the blooming-mill shears where hot steel is sheared, the blades are oil quenched and drawn to a hardness of from 444 to 460 Brinell. On the finishing mills where the steel is black, the blades have higher hardness values, 495 to 512 Brinell. A steel of this type will tend to retain its hardness and is not easily affected by the heat of the bars that are being sheared. At the strip mill it has been found advisable to keep water flow at a minimum to decrease the amount of fire-cracking on the shear-blade edges while shearing the hot steel. The life of the blade is thus materially lengthened.

The finishing mills may be put in the same class as the blooming mill, for the rolls are usually high-alloy-steel castings. The line-shafting gears and pinions on the hot beds are made from the general steels discussed previously.

There are a number of applications in the sheet mills for alloy steels. These include bar-shear knives of high-carbon-vanadium steel which can be treated to high hardness values and still retain the cutting edge without chipping. On the mills proper alloy steel is used for the hot-mill screws and hot-mill boxes. The roller leveler requires very hard rolls, and a high-carbon–low-chromium steel which will heat-treat to high hardness is usually used. A picture of a roller leveler is shown in Fig. 5.

There are in operation several normalizing furnaces for sheets which are equipped with special heat-resisting alloy rolls. These furnaces operate at temperatures of 1800 deg. fahr. and must therefore have rolls which resist scaling, even though the rolls are generally cooled by water.

In addition to the departments discussed, there are a number of miscellaneous applications in the cold-draw, heat-treat, machine-shop, and fabrication departments. In the cold-draw department a high-carbon–low-chrome steel of high hardness is used for all jaws on the benches and for the fliers. The rolls of the fliers and

FIG. 4 BLOOMING MILL COUPLING (FALK) USING CHROME-VANADIUM SPRINGS

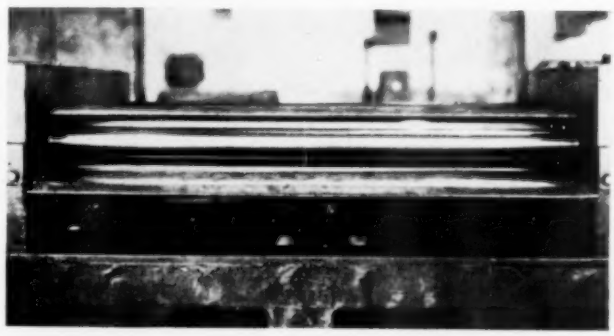

FIG. 5 VIEW OF ROLLER LEVELER ROLLS WITH ALLOY-STEEL ROLLS

straightening machines are made of high-carbon–high-chrome steel, treated to high hardness values. This steel has good wearing qualities and also hardens very deeply, thus permitting high stresses.

Stainless steels find application in the heat-treating department because of their resistance to oxidation at elevated temperatures.

CONCLUSION

We try to analyze the failures and to base the substitutions on metallurgical facts. In certain cases it is not possible to make

substitutions on straight engineering data. It is rather difficult at times to calculate with any degree of accuracy the distribution of loading or stress, and it is necessary to continue substitutions until a satisfactory material is obtained. One instance of this is the substitution of a stainless-steel shaft in an impeller pump. This pump operates constantly, but there is insufficient water supply to maintain a full head, and it has not been possible to use either carbon or heat-treated alloy-steel shafts. The stainless-steel shaft has been in operation for eight months, while previous shafts of other materials averaged one month. A picture of the impeller blade and shaft is shown in Fig. 6.

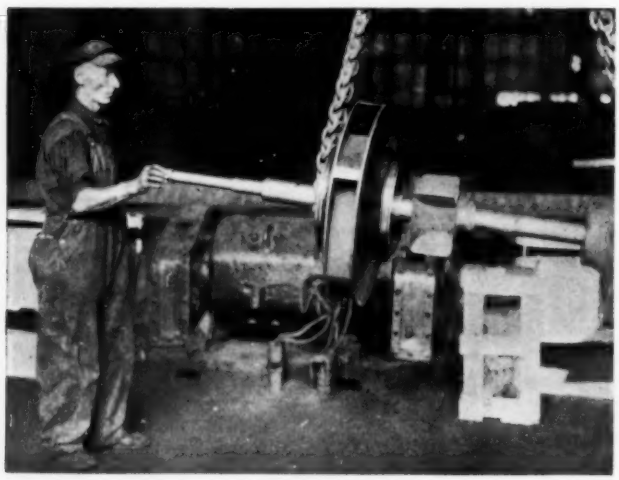

FIG. 6 IMPELLER PUMP BLADE AND SHAFT, THE SHAFT OF STAINLESS STEEL

FIG. 7 FATIGUE FAILURE OF SHAFTING, RESULTING FROM CONCENTRATION OF STRESSES

Failures can be attributed quite often to causes which can be avoided easily, such as misalignment, surface-tool marks, and insufficient radius with change of section. These conditions will cause concentration of stress and lead to a progressive failure. A typical progressive failure due to one of these causes is shown in Fig. 7, while a failure due to excessive torsional stresses is shown in Fig. 8.

A gradual building up of the alloy-steel equipment is taking place, and at present there is being used 100 tons of the various steels each month. It is felt that these changes eliminate costly breakdowns and in addition add to efficiency by giving greater production at less cost.

Discussion

W. M. FRAME.[3] The paper deals with the use of alloy steels in steel-mill equipment from a maintenance standpoint and is very interesting. It would also be interesting to hear a paper regarding the use of alloy steels in new equipment from the builder's standpoint.

A large percentage of the steel-mill equipment now in use

FIG. 8 TORSIONAL FAILURE OF SHAFT DUE TO EXCESSIVE STRESSES

originally contained very little alloy steel. This is in one way perhaps a fortunate condition. Due to modern demands much of the equipment installed a number of years ago is being operated today under conditions of load and tonnage never considered by the designers. Under such severe operation the weak points in the design are quickly indicated. As it is usually very difficult to change the design of the weak part, the solution seems to be the substitution of heat-treated alloy steels for the untreated plain-carbon steels. By the use of the proper alloy steel, the weak part can usually be strengthened enough to stand up indefinitely.

In some mills there is a deplorable tendency to replace the same weak part, time after time, with another part exactly like the one that failed. Surely this is not the most advisable thing to do. If the failure is due to the steel used in the part, the slight additional cost of alloy steel will be negligible compared with the savings effected by continuous operation. Also, the sudden failure of a part may cause the failure of other more expensive parts. Suppose a hot strip mill goes down for two hours to change a broken drive gear on a roll table. The profits lost on the material that would have been rolled while the mill was down would

[3] Otis Steel Company, Cleveland, Ohio.

probably buy several alloy gears, not to mention the operating expenses which go on whether the mill is working or not. Suppose a blooming-mill spindle pin breaks and allows the spindle to kick out and wreck itself. The cost of a new spindle would perhaps buy 50 alloy pins. This example happened recently. The plain-carbon pin was replaced with an alloy pin made of $3^1/_2$ per cent nickel steel, S.A.E. 2330, normalized, machined, and drawn.

The authors' suggestion that a separate heat-treating unit be provided to take care of maintenance work is a very good one. Often the tendency to replace failures with untreated carbon steels is due not to ignorance but to lack of material and equipment and time.

The authors mention the use of gears which have been heat-treated after machining. This is allright for cranes and many other applications, but there is a class of gears for which this method of hardening would not be desirable. For instance, in cold strip mills the gears have to be accurately cut and be free from distortion to prevent chatter marks from appearing on the finished strip. Also, wear which ordinarily would not be considered excessive must be absent from the gears on the finishing stands at least. Untreated carbon-steel gears are too soft and do not wear very long. These gears are being replaced with cast chrome-molybdenum steel and the pinions with forged chrome-molybdenum steel. The treatment is as follows: anneal, rough-machine, normalize, draw, and finish-machine. In this manner gears can be obtained much harder and more wear resisting than untreated carbon-steel gears and still be free from distortion.

The use of alloy steels is not a cure-all, and it is not economical to use them where the cheaper carbon steel will do the work. As the authors mention, failure sometimes occurs due to poor design, misalignment, sharp fillets, etc. These causes can usually be detected and sometimes corrected. However, it is believed that our maintenance costs and our undetermined losses can be materially reduced by the proper supervision and application of material to replacement parts.

The tendency of finishing-mill design seems to be toward continuous mills and multiple units in series operation. In series operation a breakdown of one unit in the series causes a shutdown of the other units. The series represents a large investment and must be kept working in order to show a suitable return. It is believed that the proper use of alloy steels will help to insure the owners against breakdown of this expensive equipment.

Charles McKnight.[4] The iron and steel equipment field has not progressed very rapidly in the use of alloy steels because the incentive which the automotive industry had has been lacking. In the automotive industry it is essential to have strength coupled with lightness. In the steel mills there have been few limitations as to weight or size, and it has been the natural tendency to obtain the requisite strength by increasing sizes. There are, however, as the authors point out, definite advantages to be gained by the use of alloy steels.

Of course, in one department of the steel industry alloy steels have been used for a long time. In this paper reference is made to the use of "Adamite" rolls. This is a metal which might be called either a steel or an iron which owes many of its peculiar properties to the fact that it contains nickel and chromium. There are other mixtures which likewise employ nickel and/or chromium, sometimes in combination with molybdenum, in the manufacture of rolls, and their use has long since demonstrated their value.

One of the newer developments in the manufacture of rolls has been the use of a high-nickel-chrome cast-iron mixture for cold rolls. In cold rolls where it is necessary to obtain a very high finish, recourse has usually been made to the hardened and ground steel rolls. These were forged from high-carbon chrome steel, hardened by quenching and ground to a very high polish. It has been found possible to obtain similar results at a lower cost in many of the sheet-mill applications by using a chilled cast-iron roll with about 5.0 per cent nickel and 3.0 per cent of chromium. In many instances the hardened and ground roll is still superior and should be used, but there also are many other places where a cheaper chilled roll is doing good work.

Mention is made in the paper in two or three cases of a normalized carbon-vanadium steel for such parts as large shafts, push-rods, and charging-machine peels. There is another steel which lends itself peculiarly to these uses. This steel has been developed in the last few years, principally for work in the locomotive field, and contains from 2.0 to 3.5 per cent nickel with low carbon (0.17 to 0.27 per cent). The advantages in its use are that, used in the normalized condition, it will develop very satisfactory strengths, but at the same time has a remarkable toughness and resistance to impact. This toughness is indicated by the fact that in a large forging a tensile strength of 80,000 to 85,000 lb. per sq. in. can be obtained with an elongation in excess of 30 per cent and a reduction of area of over 60 per cent, while the Izod impact value will run between 70 and 80 ft-lb. Steel of this sort is of value where reliability is a paramount consideration; as, for example, for ladle hooks where the breaking will probably lead to an accident having tragic consequences. It has also proved very satisfactory in large shafts where stronger and harder steels break in a much shorter time than the tough low-carbon-nickel steels.

The authors have shown the way to a more general use of alloy steels in the steel mill. It should lead to a much wider utilization of these materials by all the steel mills as there can be no question of the economic possibilities.

Recent Developments in Blast-Furnace Design and Construction

By ARTHUR G. McKEE[1] and WM. A. HAVEN,[2] CLEVELAND, OHIO

This paper deals with two recent and highly important developments in blast-furnace construction and practice; namely, the trend toward furnaces having daily capacities of 1000 tons or more, and the profitable utilization of blast-furnace gas in the firing of coke ovens, making open-hearth steel, and in the various types of heating furnaces employed in steel mills. These developments have involved certain structural changes in the stacks, which have in time necessitated changes in such auxiliaries as stock-house and blowing equipment, gas cleaners, hot-blast stoves, and boilers. These are all considered in detail by the authors.

THERE have been two recent developments of major importance in blast-furnace construction and practice; namely, the movement to larger furnaces, having daily capacities of 1000 tons or more, and the very profitable use of blast-furnace gas beyond the confines of the blast-furnace plant, for underfiring coke ovens, for making open-hearth steel, or for use in various types of heating furnaces throughout the steel mills.

These two developments have involved a number of structural changes in the stacks and have made it necessary to give much more consideration than formerly to certain auxiliaries such as stock-house and blowing equipment, gas cleaners, hot-blast stoves, and boilers.

The Furnace Stack

The ability to make 1000 tons from a single stack was accomplished rather suddenly, if not dramatically, by a radical increase in the diameter of the furnace hearth. Whereas, previously, increases in hearth diameter had been a few inches per year, in the summer of 1927 a furnace was built having a diameter of 24 ft. 6 in., which was about 3 ft. greater than that of any previous design. (Fig. 1.)

While this furnace did not immediately produce 1000 tons per day, it did produce more than 900 tons without scrapping, notwithstanding the fact that the top of the furnace had been left disproportionately small, and in spite of inadequate blast-heating facilities and an uneven grade of coke.

A matter of tremendous importance to the industry lay in the fact that this advance was accomplished without operating difficulties, and predictions were promptly made by students of the art that with higher blast temperatures and better fuel the furnace in question would easily reach the 1000-ton goal.

A few months later, under improved conditions in these respects, this furnace was consistently making 1000 tons daily, and for the year 1928 had the surprising total output of 368,000 tons or a daily average production of 1008 tons. This truly remarkable achievement by the personnel of the Jones & Laughlin Steel Company was accomplished without adequate adjustment of the other parts of the equipment to the greatly increased demands made by this large output.

It remained, then, to match this development of hearth size with a corresponding increase in other furnace dimensions as well as in capacities of the furnace auxiliaries.

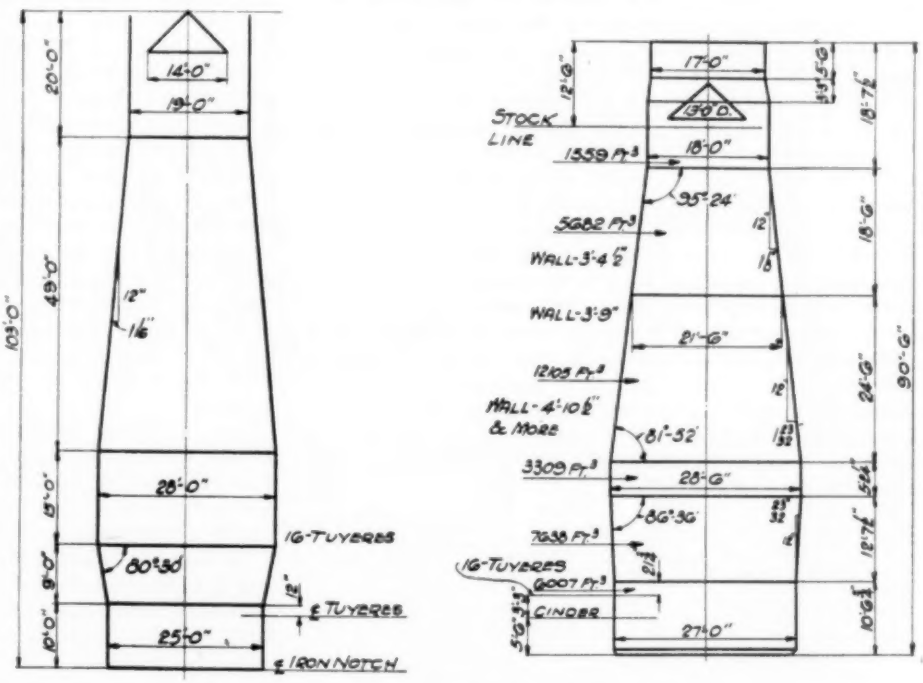

Fig. 1 Lines of Two Modern 1000-Ton Blast Furnaces

Even in furnaces of the 21-ft. 6-in. hearth diameter, there had been considerable hesitancy about enlarging the furnace tops proportionately. In many cases this was a natural consequence of the fact that the larger hearths were fitted to small stacks to avoid the greater cost of a complete rebuilding, but even where new furnace shells were installed the old conservative stock-line diameter of 17 ft. or 17 ft. 6 in. was reproduced.

It had been long the belief of the authors, however, that top development had lagged behind hearth development and had

[2] Vice-President, Arthur G. McKee & Co.

Presented at the Third National Meeting of the A.S.M.E. Iron and Steel Division, Cleveland, Ohio, September 11 to 13, 1929.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

been one, if not the most important, cause of the seriously increased flue-dust losses that have attended the large units and of the much greater volume of blast which they have required.

It is an outstanding development of recent months that three furnaces have been blown in having a top diameter of 19 ft., and hearth diameters of 19 ft., 21 ft. 6 in., and 25 ft., respectively.

In each case the practice of these furnaces has been greatly improved, particularly in the matter of flue-dust production. Losses in each furnace have been in the neighborhood of 150 lb. of dust per ton of pig iron, whereas from 200 to 400 lb. per ton is common practice with smaller tops.

On the last two furnaces mentioned another significant change has been to increase the distance between bell and stock line from the long-customary figure of 2 ft. to that of 2 ft. 6 in. The relationship between large bell and stock-line diameters has always been known to be a matter of vital importance in securing the proper distribution of stock within the furnace, and this apparently small change may well have a very great bearing upon the improved results obtained with the larger tops.

The increasing size of bells has been in itself one of the problems in connection with these large stacks. The casting and machining of 14-ft. or 15-ft. bells taxes the capacities of the largest steel foundries, but the transporting of such a casting to the furnace plant presents almost insurmountable difficulties, as it has dimensions in excess of maxium railroad clearances.

As a practical solution of this difficulty, the authors suggested some years ago the use of bells made of a central portion, to which is riveted and welded a skirt or rim of two or more pieces after delivery to the site. In two cases just mentioned the bells are 14 ft. in diameter, and when it is understood that a $13^1/_2$-ft. 50-deg. bell is the maximum limit of standard railroad clearance, we can appreciate the difficulty of transporting a $14^1/_2$-ft. or 15-ft. bell. The authors understand that one of these 14-ft. bells was delivered by barge from shop to furnace plant.

At the present time the largest furnace in existence has a 27-ft. 6-in. hearth, but the stock line is only 18 ft. Other furnace dimensions have, of course, come in for renewed study and consideration since the advent of the 25-ft. hearth. Without going into detail in each one of these cases, the authors would suggest the following figures as being suitable for a modern furnace of 1000 tons' daily capacity, and believe that these dimensions, or larger, will be recognized as standard in the near future; further it is probable that the stock-line diameter may be increased at a faster rate than the hearth diameter, until they are more nearly equal than is now the practice.

Hearth diameter	25 ft.
Bosh diameter	27 ft.
Stock-line diameter	20 ft.
Bell diameter	15 ft.
Total height	95 ft.
Bosh height	10 ft.
Straight section above mantle	10 ft.
Angle of bosh	84 deg. 17 min.
Slope of inwall	$^{13}/_{16}$ in. per ft.

It may be safely predicted that a furnace of these dimensions, if provided with lake ores of average iron content and with a good grade of coke, will produce 1000 tons of pig iron per day, and that the flue-dust losses should be very low if the downcomers are properly designed. Little or no scrap should be necessary to accomplish this tonnage, but there should be adequate provisions for heating the blast to 1500 deg. fahr., although the operator may elect to use temperatures somewhat less than this figure.

For a furnace of the size under consideration the matter of foundations is one of the utmost importance. The total load on the foundations will be approximately 5000 tons, and the foundations themselves will weigh an equal amount. Very careful study of the soil conditions is consequently called for when the matter comes up of building new or rebuilding an old furnace to these dimensions.

The number of columns and tuyeres employed is optional, generally 8 to 12 columns and 12 to 16 tuyeres.

Furnace Auxiliaries

As previously stated, the advent of the 1000-ton furnace has necessitated a corresponding increase of capacity in the furnace auxiliaries.

It should be noted at this point that none of the larger furnaces of today is a new furnace plant; all are units of old plants wherein in all cases the stock houses, stoves, and blowing equipment were originally designed and built for furnaces of 500 tons capacity or less. It is highly improbable that many additions will be made to the number of furnaces at existing plants, for the obvious reason that capacities are more readily and economically increased by enlarging the existing stacks. As is well known by every one, this has led to a rapid decrease in the total number of active stacks notwithstanding a largely increased potential total capacity and actual output.

It is of course more difficult, though much less expensive, to double the capacity of existing auxiliary equipment than it would be to build entirely new. At each plant, moreover, the problem will be different. It is therefore not possible to describe in detail the many expedients which have been practiced to keep the auxiliary equipment in step with increased stack capacities.

In general, it may be stated that the tendency in stock-house construction is definitely toward central coke bins, preferably supplemented by weigh hoppers for coke weighing, double-compartment larry cars, and double skips of large capacity. Skip hoists and bell dumping rigs are of course of increased size and electrically operated.

For blowing equipment, turbo-blowers have proved particularly well suited for the larger furnaces due to their highly efficient operation and also to the small amount of floor space which they require, so that they can readily be installed in place of the much bulkier old blowing engines which they replace. By the substitution of turbo-blowers for reciprocating engines, it is quite possible to more than double the amount of blowing capacity which can be housed on a given area of foundation or in a given building.

In a similar way modern large-capacity boilers have made it feasible to meet the increased demands of the furnace plant for steam by replacing the many small units of former days with a few very large ones, requiring much less space per unit of capacity except toward the stars, where it is readily available.

While on the subject of boilers, it may be noted that powdered coal is finding more and more favor as an auxiliary fuel for use with blast-furnace gas. The chief reason for this may be found in the fact that the switch from one of these fuels to the other is more readily effected than with stokers. At one large installation of this type the auxiliary firing is automatically controlled, and is stopped and started as the supply of gas is equal to or fails in meeting the demands of the plant for steam.

The most important developments and changes in furnace auxiliary equipment, however, have been in connection with blast-furnace stoves and gas-cleaning equipment. These subjects the authors believe to be worthy of consideration in some detail.

Hot-Blast Stoves

The matter of stove construction has been brought into prominence recently, both by the requirements of the larger furnaces and by a greater appreciation of the value of blast-furnace gas for other purposes. The one has made it imperative to secure greater blast heating capacity and the other has emphasized the

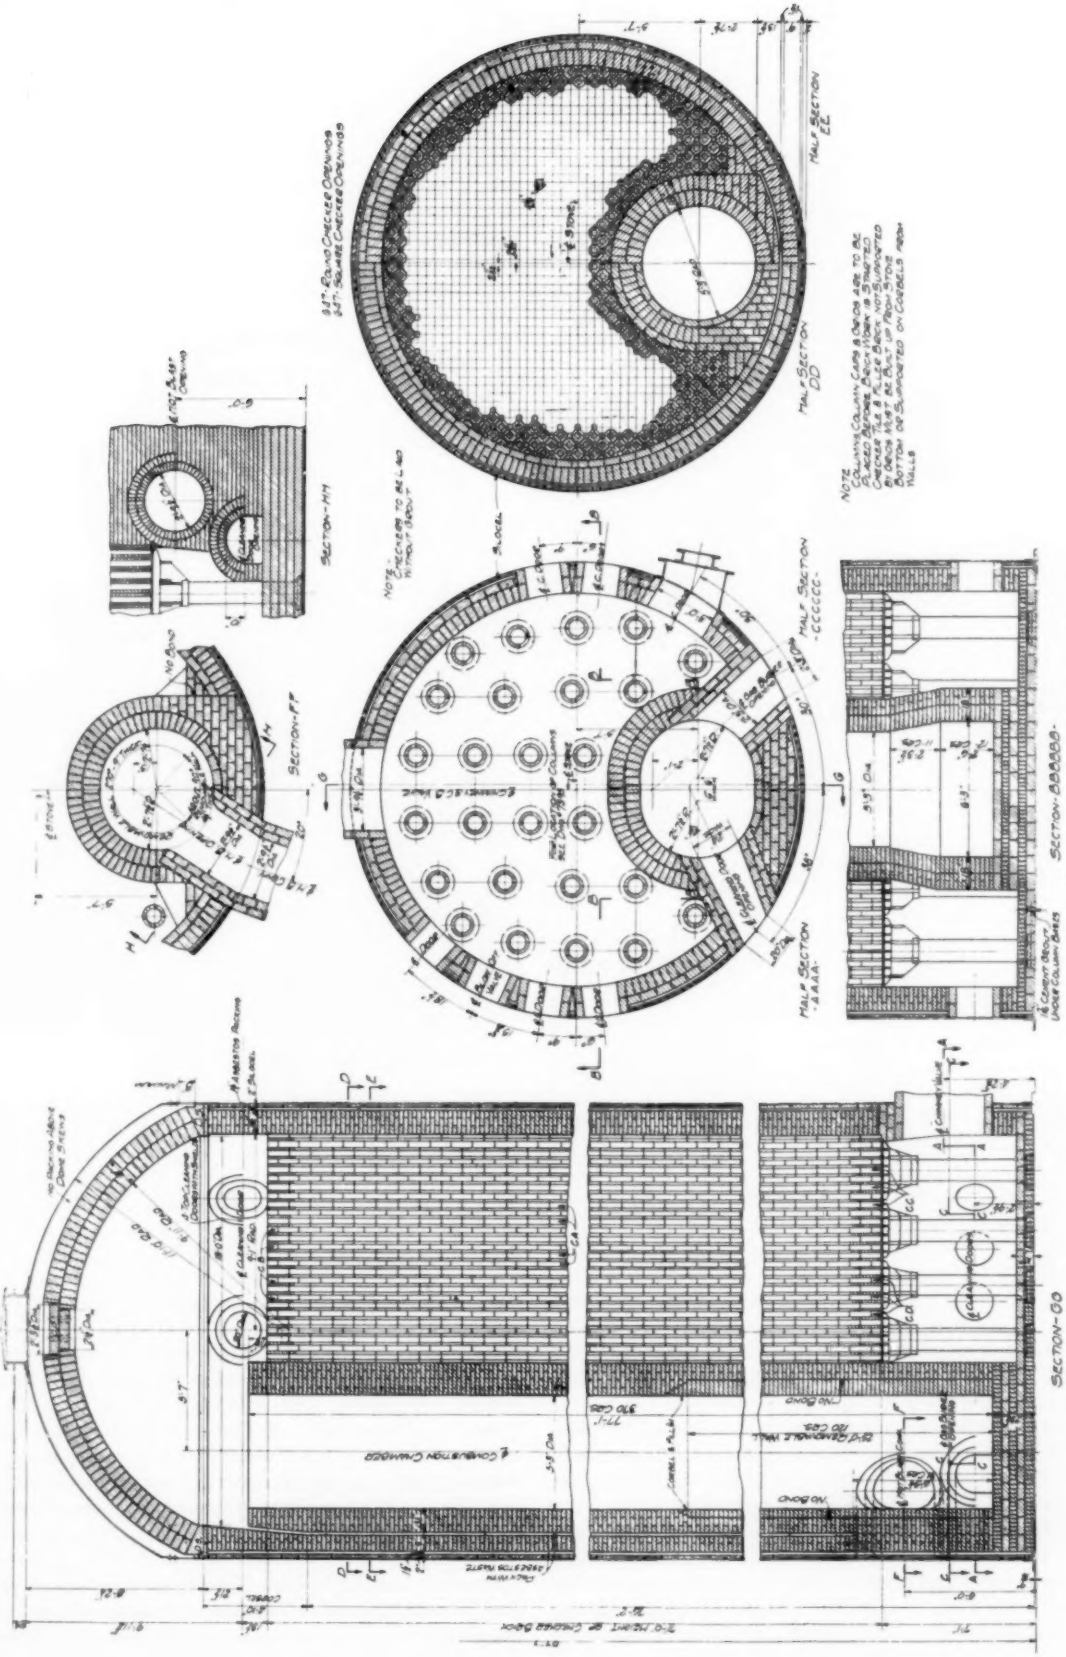

FIG. 2 SECTIONS OF TWO-PASS METAL-BOTTOM STOVE

importance of gas conservation through higher stove efficiency. Another reason for better stoves lies in the generally improved furnace practice, which has made the use of higher blast temperatures feasible. From 1200 to 1500 deg. is now common practice, which is probably two or three hundred degrees higher than the average of a few years ago.

A great majority of the older furnaces were equipped with four stoves each, which varied greatly in size and type of checkerwork. A common or average size of the old two-pass stoves would probably be about 21 ft. × 100 ft. Many of the stoves still in use

With the advent of gas scrubbers the possibility of using smaller checker openings was quickly realized, with the result that many of the old stove shells have been relined during the past decade with openings of from $3\frac{1}{2}$ to 5 in. and with brick as thin as 2 in. With construction of this type it has been possible to practically double the heating capacities at certain plants merely by relining the stoves with smaller checkers. During the same periods the use of better insulating materials such as diatomaceous earth has also accomplished a reduction of radiation losses. The use of pressure burners has further increased the capacity of existing

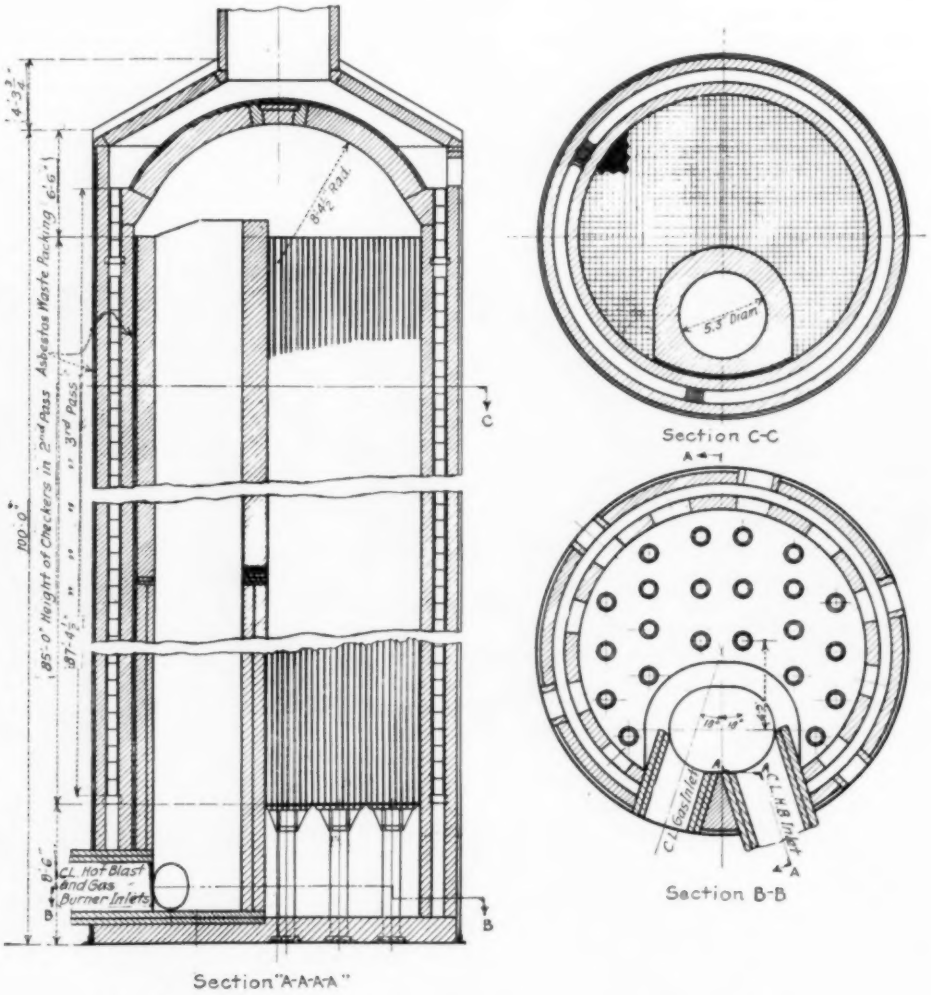

FIG. 3 SECTIONS OF THREE-PASS STOVE HAVING METAL-SUPPORTED CHECKERS

are of the McClure three-pass type, which were generally 21 ft. or 22 ft. × 8 ft. up to 100 ft. Many of these stoves were built more than twenty years ago, previous to the general adoption of wet cleaning of blast-furnace gas, and are still lined with the very large checker openings which the use of dirty gas made necessary. From 35,000 to 50,000 sq. ft. of heating surface per stove was generally the limit for this old equipment.

Under such conditions very high stack temperatures were unavoidable. In many cases the temperature of the stack gases would be equal to or greater than that of the blast leaving the stoves. Insulation was generally blast-furnace slag, and between high radiation losses and stack losses the thermal efficiency would be very low, seldom higher than about 60 per cent.

stoves, although often at the expense of stove efficiency through increased stack temperature, unless the heating surface has been largely increased so as to absorb the heat from the increased volume of hotter gas. The improvements just outlined, viz., smaller checkers, better insulation, and pressure burners, may be defined roughly as taking place in a period extending from 1914 to 1928 and contemporary with a general increase in furnace capacity from 500 to 750 tons per day.

The modern blast furnace, especially when operated in conjunction with steel plants and rolling mills, will, in all probability, soon be supplying blast-furnace gas for many different metallurgical purposes, and must be provided with stove equipment which is ample for blast heating requirements and at the same time

highly efficient in use of gas, which is in that case a very valuable product.

Radiation losses must be kept to a minimum and stack temperatures low. Checker openings must be as small and checker walls as thin as is consistent with the cleanliness of the gas to be used and the structural strength required.

About 400 to 450 sq. ft. of heating surface for each ton of pig iron produced per day is now called for under conditions of normal furnace practice. A furnace making from 1000 to 1200 tons per day should therefore have 400,000 to 550,000 sq. ft. of heating surface in its stoves, or something more than 100,000 sq. ft. per stove where the usual number of stoves is employed.

It will thus be seen that the 1000-ton furnace, together with the increased necessity for gas conservation, has called for still further improvements in stove construction.

Some builders have preferred to obtain the additional heating surface needed by building much larger stoves or by the use of extremely small checkers, as small as 1 in. in diameter. Such procedure is objectionable, however, for two important reasons. It makes imperative very complete cleaning of the gas, and the holes are susceptible to closing from any very slight shifting of the checkerwork. The resistance to the travel of the gases

FIG. 4 COLUMNS AND GRIDS SUPPORTING CHECKERS

through them is also high, requiring more pressure at the burners or a much higher stack to overcome it.

For years past the authors have recognized the fact that smaller checker openings and thinner checker walls were absolutely necessary in order to get the much greater heating surface required into our present small stove shells. At the same time they have realized that it was absolutely impossible to support such small checkers on firebrick arches and girder tiles.

In order to get the required heating surface in small checkers and to support them safely and permanently, they have developed a new type of checker support in the form of columns and high-chrome-nickel alloy-steel grids which support the entire bottom surface of the checker structure so that it is quite impossible for the checkers to shift or break down unless from the failure of the grids. (Fig. 2.)

These grids, on the other hand, are designed for a factor of safety of 15 at a temperature of 1000 deg. fahr., so that the possibility of failure of the checkers at their supports is practically eliminated.

It will be noted that each part of this stove is self-supporting and free to expand vertically, independently of all other units, so that there are no undue strains set up by unequal expansion of the different parts.

The authors have avoided the use of extremely small checkers and at the same time secured a very large treating surface by the combination of desirable features, especially the fact that the checkers may be started very near to the bottom of the stove and at the same time have unusually large passages for the gas and blast.

The checker tiles are so interlocked with each other that they cannot become displaced laterally, and at the same time the individual checker tiles are free to expand vertically without interfering with each other.

The manifold advantages of this construction will be readily apparent in that it offers strength, durability, and unobstructed access to the checker openings, while at the same time permitting a very large reduction in the more or less unutilized space below

FIG. 5 TOPS OF GRIDS SUPPORTING CHECKERS

the checkers. More even distribution of the gases over the entire area of the checkerwork also results, which tends to increase both the capacity and efficiency of the stove. (Fig. 3.)

With blast-furnace gas of the cleanliness obtained from washers of the Feld type—now in common use throughout the industry—and containing less than 0.25 grain of solids per cubic foot, it is quite feasible to use checkers as small as $2^3/_4$-in. square or 3 in. round. A 21 × 100-ft. stove lined with $2^3/_4$-in. checkers and the authors' metal bottoms and having $2^1/_2$ in. of silocel insulation will have 108,000 sq. ft. of heating surface. Four stoves of such design are probably ample to provide adequate blast-heating capacity for the largest-size furnaces while maintaining a high degree of thermal efficiency, although such a happy combination of equipment as a 1000-ton furnace and stoves of 432,000 sq. ft., has never been tried and for this reason the authors are unable to make a positive statement. However, four 22 × 100-ft. stoves would provide 480,000 sq. ft., which is just that much more. (Figs. 4 and 5).

Some actual performance data from a battery of stoves of this construction may be of interest. The following data and the illustrations which pertain to this subject are in connection with three stoves of this type which we have recently designed and built. It was found unnecessary in this case to reline the fourth stove, the very large capacity and high efficiency of the new metal-bottom stoves of only 21 × 90 ft. making it possible to get all the blast temperature desired from only three stoves remodeled in this fashion when blowing 47,000 cu. ft. of blast and making nearly 700 tons average output. Use of the remaining old stove has been entirely discontinued. (Fig. 6.)

Gas-Cleaning Equipment

Closely associated with the improvements in stove construction and particularly with the use of blast-furnace gas at coke plants and in the mills, has been the matter of better gas cleaning.

Previously the complete elimination of dirt from the gas had been held to be necessary or justifiable only when the gas was intended for use in gas engines. The Theisen drum-type scrubber was used in almost every case for this purpose. Where the gas was to be used for stoves or boilers the Feld type of washer has been most generally adopted. The cleaning efficiency of these two types of cleaners may be roughly compared by the statement

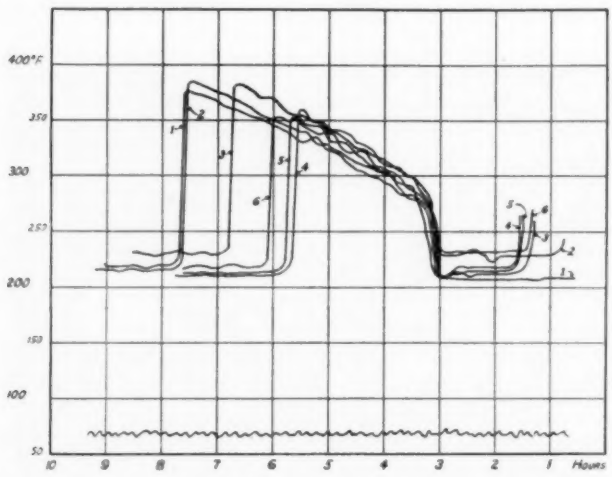

Fig. 6 Blast-Furnace-Stove Stack Temperature Chart With Successive Cycles Superimposed

that the Feld-cleaned gas will usually contain less than 0.2 grain of dust per cu. ft., and Theisen-cleaned gas less than 0.02 grain.

With Feld- or McKee-cleaned gas it has generally been possible to operate hot-blast stoves continuously for several years, oftentimes the entire period of a blast, without interruption for cleaning. Inasmuch as Theisen cleaning has been highly expensive, the power requirement alone being more than five times that of the Feld or McKee type, it may be readily understood why it has not come into common use.

The disintegrating type of cleaner is one which was developed in Germany in an effort to obtain gas of Theisen cleanliness with a smaller expenditure of power. Several German firms now make disintegrators, including Theisen, and they have come into very general use abroad. While accurate data are not yet obtainable on American practice, it is probable that their cleaning effectiveness wil compare favorably with that of the drum-type Theisens. It appears that the power requirements will be about one-half that used in the old-type Theisens.

Another very promising development lies in the application of Cottrell precipitators to wet gas. A small plant of this type used in conjunction with primary tower washers has consistently cleaned down to about 0.01 grain per cu. ft. Apparatus of this type has a distinct advantage in power and water consumption over any mechanical scrubbing device. The following table, based upon the best obtainable data, may be of interest:

	Final cleaning—non-boosting		
	Drum-Theisen	Disintegrators	Cottrells
Water required per 1000 cu. ft. of gas, gals.	10	10	0.6
Total power required per 1000 cu. ft. of gas, kw-hr.	0.1137	0.0564	0.0084

The first cost of the Cottrell equipment completely installed will compare favorably with that of the disintegrators.

It will be noted that while rapid progress is being made in the development of better and more economically operated devices, the final cleaning of gas is still quite an expensive procedure and is as yet clearly justified only where ultimate cleanliness is an operating necessity.

There is, undoubtedly, however, a rapidly growing demand for thoroughly cleaned gas brought about by the extension of its use for underfiring coke ovens and in the steel mills, which is for this country a comparatively recent innovation.

At the same time renewed and vigorous efforts are being made to improve the efficiency and decrease the investment and operating costs of both the primary and the final gas-cleaning equipment, as for instance, the Cottrell development mentioned above, and the authors have well-founded hopes of the early development and availability of further improved devices in both of these fields.

Use of Blast-Furnace Gas at Coke Ovens and Steel Plants

Until quite recently, in what might be called normal American practice, the use of blast-furnace gas has been limited generally to the heating of stoves and the generation of steam. In some few plants it has been used in gas-engine-driven blowers and electric-power generators.

The past year has witnessed the inauguration in this country of underfiring coke ovens with blast-furnace gas. Two merchant furnace plants having adjacent by-product coke ovens are now using this means to increase their revenues by releasing large additional amounts of coal gas for sale to domestic users. Both are in the Chicago district, where there is a large and profitable market for this commodity. The construction and operation of these plants have been fully described in the technical press, and the results are known to be highly satisfactory.

Coke produced in ovens heated by blast-furnace gas has proved to be of more uniform quality than when the same ovens were fired with coal gas, and the blast-furnace practice is said to have been improved as a result of the change.

Where there is a domestic market for coke-oven gas the utilization of blast-furnace gas for firing coke ovens will undoubtedly be most productive of profit. About 25 per cent of the gas produced in the manufacture of a ton of pig iron can be utilized in this fashion, which will be approximately 35,000 cu. ft. per ton of pig iron produced, and will replace and release for sale about 6000 cu. ft. of coal gas. Assuming for the latter a market value of 25 cents per M cu. ft., the gross revenue from this source will be therefore about $1.50 per ton of pig iron. If the blast-furnace gas in question were withdrawn from boilers, it would have had to be replaced with other coal, coke, breeze, oil, or some other fuel. Assuming it were replaced by pulverized coal at $3.50 per ton, its cost of replacement would be approximately 42 cents. Cost of cleaning, boosting, and distributing will not exceed $^1/_2$ cent per M cu. ft. The net credit per ton of pig iron under these conditions would therefore be $0.91 per ton of pig, and in so far as this was formerly surplus gas which was being wasted, the saving would be about $1.32 per ton of pig iron.

Where the blast furnaces are operated in conjunction with and in proximity to both coke ovens and steel plants, another very profitable means of utilizing the gas is in open-hearth furnaces, soaking pits, and heating furnaces throughout the mills. When mixed with various proportions of coke-oven gas, it has proved to be the ideal fuel for these purposes.

It has been the privilege of the authors to participate in the design and construction of the first complete American plant of this type. This plant has now been in operation for several months. It is stated by the officials of the company operating

it that the results to date have been highly satisfactory both from the standpoint of operation and the economies obtained. A brief description of the installation may be of interest.

Primary cleaning of the gas is done in the dry-dust catchers and a wet washer of the Feld or McKee type, which reduces the dust content to less than 0.2 grain per cu. ft. The gas going to the stoves and boilers is taken directly from the McKee washer.

Gas for the steel works is further cleaned in Theisen disintegrating washers to a cleanliness of approximately 0.02 grain per cu. ft. The gas is also boosted by the disintegrators to 20 in. of water pressure and discharged into a 1,000,000-cu. ft. gas holder near by. From the gas holder it is distributed through one main to the open-hearth plant, and through another to the steel mills. These are overhead mains and they have total lengths of 1200 ft. and 1400 ft., respectively.

In close proximity to each point of consumption has been located a station for the mixing of the two gases. The design of the mixing devices is such that any desired proportions of the two gases may be obtained and automatically maintained. Thus the B.t.u. value of the gas may be correctly adjusted to the particular requirements of each steel-making or heating unit.

The peculiar advantages of a mixed-gas system will be readily apparent when one stops to consider that probably no two of the various heat treatments which are employed in the manufacture of steel products will call for the same intensity and quantity of heat, and that mill practice must be greatly improved when the B.t.u. value of the fuel employed is accurately adjusted to each particular use. The two fuels, blast-furnace gas of about 90 B.t.u. and coke-oven gas of about 550 B.t.u., furnish an admirable means of accomplishing an ideal fuel by mixing.

At the plant in question the B.t.u. values in use at the present time are as follows:

Open-hearth furnaces	250
Merchant-mill heating furnace	325
Soaking pit	90
Sheet and pair furnaces	150
Sheet box annealing furnaces	125
Sheet galvanizing pots	90

The monetary advantages which may accrue from the installation of a complete system for cleaning and for distributing blast-furnace gas to the steel mills may only be arrived at by a very careful examination and study of the economic and operating conditions which obtain in the plant and locality under consideration. Among the factors which must be taken into account are the quantity and quality of the blast-furnace gas available and its value for steam raising based upon the cost of steam coal; the supply of coke-oven gas and its commercial market value, if any; the fuel practices in the plants under consideration and the cost of producer gas or other fuels which it is expected to supplant with mixed gases; the cost of buying or producing electric power; and, finally, the cost and practicability of constructing the cleaning and distributing system.

In general, however, it may be stated that where there is no domestic market for coke-oven gas, any steel plant having two or more blast furnaces and by-product coking capacity sufficient for their needs cannot afford to overlook what in many cases will prove to be a highly profitable means of reducing costs, increasing output, and improving the quality of their product.

Investigations by the Bureau of Mines

Another matter which the authors would commend to the most careful consideration of all blast-furnace men is the blast-furnace research work which has been done during the last few years by the very competent engineers of the Bureau of Mines, with headquarters at Minneapolis, Minnesota.

In their opinion this is the most important work which has been done by any group of men for the advancement of the art of smelting iron ore since the days of Sir Lowthian Bell, and all should study most intimately all of the information and data which have been gathered by these engineers.

In this connection all should realize the fact that these investigators cannot be expected to be intimately familiar with all of the practical operating facts and difficulties of blast-furnace construction and operation, and for this reason it is particularly the obligation of the operators to study the information thus made available and draw the logical conclusions therefrom to the end that the construction of blast furnaces and the manufacture of pig iron shall profit in the highest possible degree from this valuable work.

The last reports available seem to the authors to indicate very conclusively the desirability of larger stock-line areas so as to reduce the velocity of the gases through the stock at this point, and also the desirability of a greater distance from the stock-line wall to the edge of the bell so as to make the percentage of voids more uniform from the periphery to the center of the furnace and decrease the wide difference in gas velocity between that near the wall and that at the center of the furnace.

Steeper bells, a greater travel in opening, and a quicker movement of the bell from the closed to the open position are also potent factors in securing a more uniform radial distribution of the coarse and fine particles of the stock and the resultant effects of more uniform rate of gas travel and lower flue-dust losses.

If these results are being secured and may be secured to a greater degree by the use of larger top diameters and bells smaller in proportion to the stock-line diameter and other changes proposed, then the authors would reasonably expect that their latest blast-furnace construction with large stock lines and proportionately smaller bells should give a higher thermal efficiency than was previously possible and the whole industry should benefit thereby.

It is sincerely hoped that there may be a still closer cooperation between blast-furnace operators and builders and the Government engineers, and a much more intensive study of the reports made available from time to time by these experts of the Bureau of Mines. The authors are fully convinced that such cooperation and study will result in very great benefit to the whole industry.

The authors are satisfied that by all odds the greatest benefit that can result from papers of this sort is due to the discussions which they bring forth. For this reason they hope that a free discussion may follow, and particularly that any who may disagree with anything in the paper may fully state their opinions, as they want, above everything else, the most accurate information obtainable.

Conclusion

From the collection of information which the authors have been able to present, it is evident that the industry of making iron is making remarkable strides both in output and in the efficiency of the operation.

All have reason to feel proud of the achievements of the past year or two, and although the industry is now in a high state of development and efficiency, the authors sincerely hope that other valuable improvements may be forthcoming in the near future.

Discussion

H. J. Allen.[3] Regarding size of stacks, it is interesting to note that the large increase in diameter of hearths, originating

[3] The Bourne-Fuller Company, Cleveland, Ohio.

about two years ago, and following very closely certain experimental data presented by the U. S. Bureau of Mines showing that the penetration of the blast of oxygen in front of the tuyeres was limited very much below the radius of the hearth. This paved the way for belief that larger hearth furnaces would function properly without fear of unequal blast distribution at the hearth.

Larger furnace tops have been used recently in the South with success, although Northern operators have been rather hesitant to try them. But from the results of the three furnaces referred to in the paper, they will probably become almost standard.

Another interesting trend in design is that furnaces using Lake ores, and constantly being blown harder, are becoming straighter —that is the bosh angle is larger and, in some cases, the batter of inwall smaller. Heights of furnaces are not increasing.

The turbo-blower has become the standard, and units are being built today of so large a size that a single reciprocating engine to do the same work would be entirely impracticable.

Regarding boilers burning blast-furnace gas, installations are operating efficiently where the air for combustion is preheated from the heat in the stack gases, thereby increasing the boiler efficiency.

As the first and most economical use of blast-furnace gas is in stoves, some construction has come in for considerable development in recent years. For this reason operators are constantly striving for higher blast temperatures, combined with high stove efficiency. This, the authors have stated, has been made possible by improved gas-cleaning equipment, aided by pressure-type burners, in connection with stoves having checker openings of small area and comparatively thin walls. Two-pass stoves of center-combustion-chamber design, the writer believes, will become more predominant, as the pressure burner tends to give uniform distribution of the gases in the checkers, and the construction of the masonry in the center-combustion-chamber stove in the checker section is much freer from operating troubles than in a side-combustion-chamber stove. A stove of this design is just being completed by the concern with which the writer is connected, and uses what is known as a Whelpley checker, which is one of T shape. The shell size of this stove is 20 ft. × 90 ft., has 4-in. square checker openings, with $2^1/_2$-in. checker walls, and will have a heating surface of 68,000 sq. ft.

The authors' metal support for checker areas in stoves, the writer believes, is one of the notable contributions to stove design in recent years, and furnace operators are watching its performance with much interest.

Another principle of stove design that is being applied in some new stoves is decreasing the areas of the checker openings at intervals from top to bottom of the checkers, in order to approximate a constant rate of travel of gas and air through the checkers.

One development that deserves mention in dealing with blast-furnace equipment is the new type of electric-driven mud gun, developed by Mr. John Hopkins of the American Steel and Wire Company, of Cleveland. This gun has made it possible to stop the iron hole without reduction of the blast, and to entirely complete the operation through remote control. Mr. Hopkins has also developed a diverging-nozzle tuyere, for which it is claimed that lower blast pressures are obtained and tonnage is somewhat increased.

HARVEY B. JORDAN.[4] Under the discussion of the furnace stack, the authors give recommended dimensions for a 1000-ton furnace. While, to the writer's knowledge, there is not at the present time a plant having a furnace with these particular dimensions, he is sure there are many in agreement generally on this proposal.

[4] Superintendent, Central Furnaces, American Steel and Wire Company, Cleveland, Ohio.

With the authors, the writer pleads that due consideration be given the apparent value of a greater stock-line diameter. The $^{13}/_{16}$-in. slope per foot of the inwall may perhaps be a sacrifice, and yet commendable if necessary to obtain the 20-ft. stock-line diameter.

In conjunction with top enlargement, some operators and engineers have increased the annular space, which is in itself a progressive step, theoretically and practically sound. There has been a little doubt in the minds of some of these men as to the percentage of value which should be attributed to each of these changes. Just recently, one of the leading operators, without any other adjustment, increased the annular space. This was done on a new, modern furnace after it had been operated for a satisfactory period on what many considered a standard space. The result of this one change was very profitable. The limit to which such enlargement can be profitably extended on the large, modern top type of blast furnace, operating on Lake ores, is not definitely known.

With the advent of larger hearths and larger stock lines, due consideration must be given the vertical measurements. The opportunity which the writer has had to observe the operation of two furnaces of the same cubic-foot capacity operating on the same material, but with a difference of 5 ft. in height, urges him to suggest that the large furnaces be constructed to at least 100 ft. in height.

For several months the Carnegie Steel Company, at its Ohio Works, has had in successful operation a furnace with a 25-ft. hearth diameter, a 19-ft. stock-line diameter, a 14-ft. bell diameter and a height of 103 ft. While he does not have at the present time the practice figures on the operation of this furnace, the writer ventures to state that the results obtained are most pleasing to the management.

In late years there have been many changes in bosh design and construction. These modifications, together with various methods of operation, have produced important results. We do not yet have for use on the bosh, however, a novel design of water cooling which offers to the operator the advantages without the disadvantages of the present-day system. That eventually such difficulties will be largely overcome should not be an exaggerated prediction.

Gas cleaning is an expensive necessity. The economical recovery of the iron-bearing material in the gas-washer water is an important problem. The burdens upon these two operations should be decidedly reduced by the progress in the reduction of flue dust, to which phase of the gas problem our attention should also be attracted.

Among the many improvements in the auxiliaries of the blast furnace are the developments of the clay guns for closing the iron hole. The most noteworthy of these in the past year was the introduction of the pedestal, crane, and screw gun, all operated electrically. By the use of electricity, many have witnessed an innovation in iron hole practice.

The past few years have also shown greater activity in the thought and practice relative to the introduction of the air into the furnace. Among other things developed have been the diverging-nozzle tuyeres. These tuyeres have been used in some instances with satisfactory results by providing an aid in the initial directing of the gases.

Of late there has been a gradual but decided trend toward the use of large hot-metal ladles. The National Tube Company at the National Works plant has operated two furnaces, using large ladles, making the novel scrap production of three pounds per ton of pig iron.

On the subject of the use of blast-furnace gas at coke ovens and steel plants, and the marketing of coke-oven gas, the authors have offered a comprehensive account. The National Tube

Company at its National Works is pumping surplus coke-oven gas into the old McKeesport gas basin. The gas is then withdrawn from this basin as required. This procedure necessitates a suitable geological structure. The efficient utilization of such gas in some districts, when in many it is partially wasted, is a progressive step of which those responsible may be justly proud. These performances should furnish the incentive for the purpose of utilizing such gas in other districts where practicable.

The six-day utilization results in one-day inefficiency. Where such one-day inefficiency is not excessive, and entirely for the benefit of labor, these low losses are justified. However, generally the talented of our industry have before them, yet unsolved, the seventh-day utilization of these by-product gases.

T. L. Joseph.[5] As regards larger stock-line diameters, through the cooperation of several blast-furnace operators the Bureau of Mines has been able to explore the conditions inside of several furnaces. This is done by drilling a hole in the side of the steel shell and extending water-cooled tubes into the charge at varying lengths from the periphery to the center of the furnace.

A very great difference was found, for example, in the velocity of the gas at the wall and at the center of the furnace, a great variation of temperature, and a substantial variation in gas composition. And in regard to the gas velocity at one furnace it was found that in the center near the stock line the gas was moving at a velocity of over 400 ft. per sec., whereas along the wall it was traveling about 80 ft. per sec. What has been found particularly confirms the wisdom of this step of increasing the diameter of the stock line.

Arthur J. Boynton.[6] The paper has discussed in an interesting manner the question of correct diameter of the blast-furnace stock line in proportion to the other dimensions of the furnace and has very correctly stated that these proportions are now of extreme interest to blast-furnace designers and operators. The possibility of obtaining thoroughly satisfactory distribution of the materials making up the stock column becomes progressively less as increase in the diameter of the stock line proceeds, and it therefore seems quite probable that other means besides those of variation of proportion between bell and stock line will require to be employed with the wider stock line which is now definitely being tried. The writer will give his view as to an alternative method of obtaining correct distribution.

There existed a period of several years' duration within which the shape of the stock of the blast furnace above the bosh was, in its essential dimensions, standardized. The total height of the furnace was in almost every case 90 ft., the bosh diameter was 22 ft., the stock-line diameter 17 ft., and the bell diameter 13 ft. The taper of the stock line was $^3/_4$-inch per ft., and the chief variation in the furnaces of the Steel Corporation as built in different plants lay merely in the respective lengths of the upper cylinder at and above the stock line and the lower cylinder immediately above the bosh. These proportions were gradually arrived at with a stationary bosh diameter and height of furnace by successive increases in the diameter of bell and stock line. Taking into consideration the conditions with respect to blast temperature and quality of fuel, furnaces of this size, once the diameter of the hearth had been increased to 18 ft. 6 in. or thereabouts, showed an all-around performance with respect to fuel economy and production of flue dust which was probably more satisfactory than the average of records which have been made since. With respect to the production of flue dust, records are in existence which, while confined to the production of dry-flue-dust recovered from dust catchers, form a guide as to the relative excellence of practice then and now.

When the tendency toward larger hearths than could be combined with a 22-ft. bosh manifested itself, the stock line was for a considerable number of years allowed to remain at 17 ft. diameter and the bell at 13 ft. The tonnage of the furnace increased rapidly as the bottom dimensions were enlarged and the relative area of top to bottom became very considerably less than it had been formerly.

The limitation of increase in the top diameter is based on many and complicated considerations. The distribution of ore over the working annulus of the furnace depends in part on the physical character of the ore with respect to fineness and moisture content and in part on admixture with the coke charge or coke and limestone charge. With the same size of charge the radial distance over which ore is scattered is independent of the size of the top and the proportion of the total diameter of the furnace which is occupied by the ore charge decreases as the diameter at the stock line is enlarged. Apparently, also, the width of the working annulus at the tuyeres is independent of the diameter of the furnace and to some considerable extent independent of the volume of wind blown, the latter of these two statements being in accordance with the researches of the Bureau of Mines. These researches and their determination that the active working part of the hearth was confined to an annulus in front of the tuyeres seem to explain the inability of the American blast furnace to operate otherwise than with an ore charge arranged in annular form at the top. Supplementary to the researches of the bureau are, however, the observations which have been made at the furnace itself. It has long been known that the temperature of the center of the hearth or of any point inside the active area in front of the tuyeres was lower than the temperature at the tuyere area. This can be determined by a steel bar put into the furnace, as was often done. The driving of the bar also gave a practical illustration to the limit of combustion, as subsequently determined by the Bureau of Mines.

In view of the lower temperature and apparent lack of motion existing in the middle of the hearth, the placing of ore in the furnace above this relatively cool and inactive hearth zone naturally results in coldness of any iron which melts and trickles to the bottom of the hearth within it. It has accordingly long been understood that ore projected into the middle of the furnace was productive of a cold hearth.

The researches of the Bureau of Mines, and particularly those of S. P. Kinney, have determined a relatively rapid rate of descent of the materials composing the charge within the annulus around the furnace which corresponds both to the active tuyere zone and to the location within the furnace of the ore as charged. This condition even with a relatively small hearth existed within the writer's observation. For example, when a blast furnace is filled cold, the material in the top of the furnace always forms an inverted cone with the high point next to the walls. If the furnace is blown for any considerable number of minutes without recharging, this cone disappears and the height of the stock at the walls of the furnace is no higher than in the center. Further blowing without charging brings the level of the stock at the walls to a point considerably below that at the center until finally, if a furnace is blown down to the bosh, the remaining stock will form a cone with the apex in the center of the furnace. The writer also has witnessed a demonstration of the same thing at times when a brick lining was being torn out of the blast furnace and has seen a dimple in the brickbats over each tuyere as the men hoed the bats through the tuyere breasts, the height of the brick column in the furnace being at the time 40 ft. or so above the tuyeres.

It is accordingly apparent that recent scientific research and

[5] U. S. Bureau of Mines, Minneapolis, Minn.
[6] Vice-President, H. A. Brassert & Co., Chicago, Ill.

practical experience, not only with the blast furnace, but with structures of similar shape used for gravity bins, coincide in their indication that flow of material within the blast furnace is most rapid along the walls. Exact knowledge as to the speed of the center of the stock column is lacking. It is, however, presumably very slow and decreases in speed from top to bottom.

The researches of the Bureau of Mines, excepting in some cases, where less than ordinarily steep batters of the inwall of the furnace have been employed, indicate a flow of gas within the central part of the furnace which is more rapid, hotter, and higher in carbon-monoxide content than is the gas which comes up through the outer annulus which contains the ore. This condition is natural and inevitable. The coke gets to the center of the furnace by sidewise travel down the inverted cone, to which reference has previously been made, and is consequently composed of the coarser coke in the furnace charge. The resistance to the passage of gases in the outer annulus is increased by the presence of ore and by the relatively small size of the coke. The consequent effect is that of a central chimney which forms a bypass around the ore for the reducing and heating gases.

This bypass naturally increases in extent and in seriousness as the diameter of the stock line is enlarged. As previously stated, the width of the annulus within which ore may be placed by the ordinary bell-and-hopper action is not increased by increase in size of the stock line, although it may be increased in some considerable measure by enlarging the size of the charge. The limit beyond which increase in the diameter of the ore annulus is undesirable is related to the diameter of the lower working annulus in front of the tuyeres, which in all probability corresponds to what has always been called "penetration."

From the foregoing statements it seems evident that such an increase in the stock line of the furnace as would be required to restore the former proportions of the 22-ft. bosh diameter and 17-ft. stock line diameter are not possible without a radical change in the stock column. The desirable diameter of stock line based on the old experience would be as high as 22 ft. in some of the larger furnaces, either built or proposed. This is at least 2 ft. beyond any stock-line diameter which has been projected within our knowledge. It is accordingly apparent that, if mechanical considerations permitted, it would be desirable to build a firebrick pier in the middle of the furnace and to operate an annular structure. While such a conception is evidently not practicable, it is interesting to note that the United Gas and Improvement Company of Philadelphia, while operating water-gas sets through tuyeres instead of a bottom grate extending across the entire bottom, found a decided advantage in exactly such a central firebrick pier and patented the construction. The reason for this was that, with the limited amount of action obtained from the tuyeres of the water-gas set, the center of the charge was inert, relatively cold, and not gasified.

So far as can be seen, the only possible means of producing a condition in the furnace which prevents excessive central bypassing of gas with a stock line of desirably large diameter lies in the creation of a central column within the furnace with relatively small coke screened from the main charge and put into the furnace from time to time as required. The amount of coke so charged and its relative fineness are matters which must be determined by experience. Evidently the coke must not be so fine as to be impervious to a sufficient amount of gas to bring it to the hearth temperature in the course of its descent. Practically, it should be large enough to accomplish this purpose and no larger. The amount of gas which travels up the center of the furnace would then be regulated by the sizing of the central column of coke.

The size of the central column within which such coke is charged is also subject to variation by changes in the hopper which forms the means of distributing the finer coke. The amount of fine coke required will depend on the relative rapidity of descent in the middle of the furnace to that along the walls.

After sufficient experience with respect to size of coke and diameter of the central coke column has been gained, it would seem to be entirely feasible to restore the relative dimensions of stock line and bosh which formerly existed or in all probability to bring these dimensions closer together than was formerly possible. It must be remembered that in the former practice the open central bypass for hot rich gas existed in a very considerable degree.

A consideration of relative areas is interesting in this connection. The area of a 17-ft. circle is 227 sq. ft. The area of a 22-ft. circle is 380 sq. ft. The area of a 12-ft. circle is 113 sq. ft. It would consequently be possible with a 22-ft. stock line to blind the area of a central 12-ft. circle and still gain in effective area within the top of the furnace. This, however, is not proposed, since a considerable amount of gas would necessarily proceed up the center of the furnace. Based on relative areas, which would then become more truly effective than at present, the decrease in the average velocity of gas would be over 40 per cent, while the effect on flue-dust production would be many fold greater than the decrease in velocity.

Another advantage of the proposed construction, and one which with coarser ores would form its primary object, is the enforcing of contact between ascending gas and descending ore in as large a proportion as possible. The effect of this gas contact is certain to be favorable to the fuel requirement of the furnace.

An additional benefit to be derived will be the elimination of the smaller sizes of coke from the annulus in front of the tuyeres. This is universally recognized as desirable to a point which makes comment superfluous.

Owing to the conditions which have generally existed, it has become customary to reckon the capacity of a stove installation in terms of square feet of heating surface without reference to other conditions of construction and operation. It is evident from the foregoing discussion that the effectiveness of heating surface is influenced, not only by its disposition in the individual stove with reference to size of passages and effective thickness of brick, but also by the number of stoves within which it is disposed. The larger the units and the less their number the more effective will be a given amount of heating surface, other things being equal. It is consequently necessary to take into consideration, not merely number and size of units, which should be as large as the general condition of the operations require and as few as continuity of operation permits, but also the disposition of the heating surface within the individual unit. When all the conditions of heat transfer are considered, it is possible to build a stove with maximum heating surface which will be less effective than one of smaller heating surface, but designed with more skilful consideration of size of flues, thickness of walls, and velocities of gas and air.

With reference to the number of stove units which should serve a single furnace, theory and experience both show that the use of more than two stoves is attended with considerable heat losses as well as unnecessary expenditure for equipment. With regard to the first consideration, it is evident that such advantages as are gained by high velocity of heating gases are almost completely lost if the gas is divided between two or three stoves instead of being concentrated in one, and that heat transfer will be correspondingly less rapid and satisfactory. The volume of gases under standard conditions of pressure and temperature will be only about 54 per cent of the corresponding volume of the air. This difference is lessened in a considerable degree by the higher average temperature of gases compared

with that of air, so that the actual average velocities vary by only approximately 31 per cent. Where two or more stoves are used on gas, design for the sake of high velocities ceases to apply to the heating phase of stove operation. It is also evident that losses through radiation and leakage are considerably reduced in a two-stove operation.

The hesitancy in building for two-stove operation is based on two practical difficulties which have always existed, but which are now definitely capable of being overcome. The first of these results from the use of gas insufficiently cleaned to guarantee the operator against the necessity of cleaning a stove and repairing fluxed brickwork within the course of a blast-furnace campaign. The second difficulty is structural and, generally speaking, results from high temperatures in the bottom of the stove, which result in deterioration of the supporting construction members to a point which requires repair. The first of these difficulties requires only the fine cleaning of gas by means which have been demonstrated, while the second requires merely the construction of stoves of correct design and sufficient size to prevent excessive temperatures at the bottom. Trouble due to leakage of valves is too insignificant to justify the erection of a third stove, especially when one considers that a change of hot or cold blast valves requires taking the wind off the furnace whether there be two stoves, or three, or four. Where three stoves exist, or where they are provided as a precaution against interruption to operation, they should, if correctly designed, be operated with one stove on air and one on gas, with the third stove in reserve. In this way the full benefit of smaller radiation losses, less leakage, and wear and tear on valves can be realized.

A practical illustration of the principles which have been discussed may be cited from experience which has been had in many locations where furnaces have been provided with five stoves. In almost every case, at one time or another, the attempt has been made to increase the blast temperature by blowing through two stoves at once. Such a procedure doubled the quantity of hot brickwork in contact with the air, at the same time reducing the velocity of the latter by half. It is believed that no case exists in which any marked increase in temperature was obtainable by blowing through two stoves, even though the temperatures of the brickwork were capable of being maintained by excessive use of gas in three stoves. Generally speaking, the blast temperatures where two stoves were put in blast at the same time was less than that possible of attainment with the blast going through one stove. This phenomenon, which appeared mysterious to many operators a decade ago, is entirely in accordance with the discoveries of recent research.

The provision of cast-iron regenerators in series with the firebrick stoves is complicated in operation and mechanically undesirable. They also fail to increase the maximum temperature within the stove and for this reason are of little use in the creation of higher blast temperatures. The purpose which was sought to be fulfilled by the metallic construction is in large degree served by small passages and high velocities in the cooler portions of the stove, combined with an increased heating surface. However, the question as to whether the refractory stove designed with reference to scientific principles will continue to be used as at present will depend in considerable measure on the future blast temperatures which the operator desires to generate. With cool blast-furnace gas and cool air going into the stove, the temperature of combustion is not sufficiently above that of the hot blast to make the stove a truly efficient heat exchanger. The evident remedy lies not in further changes within the stove itself, nor in continuous increase in size, but in the preheating of the air and gas for combustion by means of waste chimney gases. By this means the temperature of the burned gases entering the checkers can be raised to any point which the brickwork will stand, and hot blast of any conceivably desired temperature may be readily created by the use of stoves considerably smaller than would otherwise be required. It is probable that the addition of heat exchangers to stoves of present size or of less size than some stoves at present projected will be found to be the most economical means of obtaining high blast temperatures. It is to be noted that such a procedure, in common with the other developments which have been discussed, is only feasible with use of fine cleaned gas from which all dirt practically capable of adhering to the surfaces of the stoves has been removed.

J. L. Mauthe.[7] There really is no rigid rule for large bell and stock-line clearances. The experimentation to date has not been of long enough duration to determine the practicability of increased clearances. Justifiable as it may seem, it will only be determined after a period of low, medium, and high blowing rates to ascertain, if possible, the critical velocity where best results are obtained.

All experienced blast-furnace operators know the effect of getting too much ore into the center of the furnace. What the possibilities will be with an increased stock-line diameter, maintaining the present size of the big bell, will only be determined through experiments, as stated above, unless the Bureau of Mines shall be able to conduct experiments that will determine definite results. We who have tinkered with fine materials are not quite ready to agree that this increase will eliminate the flue dust, inasmuch as in furnaces with the same lines and under the same blowing conditions a change in the ores has decreased the flue dust from 600 lb. to less than 100 lb. per ton of iron.

In the writer's opinion, we have not analyzed our raw materials thoroughly enough to determine whether an increase in the stock lines will be sufficient to reduce the flue dust. Some reliable test is needed, such as a plasticity test or something similar, which will determine the flue dust producing abilities of an ore.

F. G. Cutler.[8] With reference to the employment of a larger stock line, it may be stated that the Tennessee Company has had in operation for a year two new furnaces that are identical as regards bosh and hearth diameter, and reports are to the effect that the one with the larger stock-line diameter produces very much less flue dirt.

Authors' Closure

Mr. McKee. The difficulties which have been predicted by one or two of the discussers due to increasing the stock-line diameter may be found to be overestimated. It is doubtful whether there will be any serious difficulties since the experiments by the Bureau of Mines have indicated how we can very accurately determine and provide for the degree of distribution of the ore across the diameter of the furnace to such an extent as may be found desirable for these changes.

In other words, if the differential between the bell and stock-line diameters is increased, the distribution of the ore will be somewhat more toward the center of the furnace. If the bell is operated more quickly, there will be an added effect in this direction; if the bell is made steeper, the same result will be obtained, and likewise if it is made to travel farther, and that indicates, it is believed, that we can have a very accurate control over the distribution of the ore toward the center of the furnace, and the experimentation recommended by Mr. Mauthe to determine just what distribution of the ore toward the center of the furnace is

best for the different kinds of ores, is something that will be most valuable to the industry.

The suggestion made by Mr. Jordan that the furnaces be made still higher than suggested in the paper is a valuable one.

The present author was the engineer who laid out the first and up-to-date the tallest furnaces in the country, or in the world, namely, the original Youngstown furnaces, which were 107½ ft. from the iron docks to the top platform. These furnaces at that time were a distinct failure. They were too high for the practice current at the time, but that does not in any sense indicate that with the advance in the art they are too high for the conditions as they are today, and it is believed that experimentation and careful observation to determine the best height will be a very valuable contribution to the art.

The authors wish to thank Messrs. Frame and McKnight for their assistance, and are in agreement with their statements.

Protection of Movable Material-Handling Bridges Against Windstorm Hazards

By C. O. BURTON,[1] DULUTH, MINN.

Present-day speeds and efficiency in handling enormous tonnages of bulk materials, such as coal, coke, ore, crushed stone, etc., have been made possible only by the development of modern types of material-handling bridges. Such bridge structures now seem to be absolutely essential in the operation of coal docks, blast furnaces, and steel plants for unloading, stocking, and reloading the bulky raw materials of industry. Since they are so indispensable, it follows that their protection against all possible causes of loss or damage becomes of vital importance. By reason of their great length and height, such bridges present large wind-resistive areas, making them particularly susceptible to windstorm damage. This paper discusses some of the factors of design and construction that affect the safety of these structures, and describes and discusses the special equipment designed to increase the operating safety of bridges. The author tells of the development of material-handling bridges, and their constructional elements, so that the more specific features of bridge protection against storm damage may be better understood.

GROWTH of the coal-handling industry at the head of Lake Superior, ports of Duluth and Superior, undoubtedly parallels in many ways the early and modern development of coal- and ore-handling equipment in other industrial sections of this country. Prior to about 1880 coal received by boat at the Duluth-Superior harbor was handled almost entirely by hand. It was hoisted, first by horses, later by steam hoists, in tubs filled by hand shovellers in the hold of the boat, then transferred by wheelbarrows or hand-operated dump cars to the receiving dock. In 1883 eight wooden bridges of about 150-ft. span were erected at one dock, with steam-driven hoists and rope-operated trolleys handling a one-ton tub. These bridges were moved along the dock by hand power, and were the first at the head of the lakes.

Steel bridges followed and electrical drive began to replace steam operation. The first electrically operated bridges were apparently those erected at Duquesne, Pa., in 1895. Not until 1902, however, did the first electrically operated man-trolley bridges appear. Three stocking and reclaiming bridges were then built for the North Western Fuel Company of Superior, Wis., and these are said to be the first of their type in the world. These were used for stocking and reclaiming only, the unloading of the boat being done by a group of four hoisting towers.

In 1909, Heyl and Patterson built the first man-trolley bridge at the head of the lakes for doing all the work connected with unloading from the boat, stocking, reclaiming, screening, and loading into cars for shipment. This bridge had a 5-ton clam-shell bucket. Soon after 1910 a large number of other bridges were built at the head of the lakes, nearly all of them of the modern man-trolley type. One of these bridges on the same dock of the North Western Fuel Company, on which the first three man-trolley bridges were erected, is claimed to be the largest coal bridge in the world. It has a single span of 551 ft., is 712 ft. long, 86 ft. from dock floor to lower chord of the truss, and about 130 ft. high to the top chord. This bridge alone, with only two men per shift for its operation, can unload a 10,000-ton boat in less than 24 hr. While this development was going on in the coal-handling industry, similar advances were in progress in other parts of the country, notably with the handling and storing of iron ore at the great iron and steel centers. As a definite illustration of this growth, there are now in the eight states of Minnesota, Wisconsin, Illinois, Missouri, Indiana, Michigan, West Virginia, and Ohio about 387 movable coal-, stone-, and ore-handling rigs, of which 210 are bridge structures and 177 towers or unloaders of various types. Over 50 of these bridges are located at the head of the lakes, Duluth and Superior. Many more bridges are included in Pennsylvania, New York, Massachusetts, Maryland, and other Eastern states, as well as a considerable number in Canada, and a scattering distribution in foreign countries.

The cost of a modern man-trolley bridge of medium or large size will range from $200,000 to $300,000 and upward. Individual docks or steel plants may operate as many as 9 or 10 of these structures. This great investment alone represents sufficient reason for the adoption of all practicable safeguards against operating disasters. But the original cost of the bridge alone cannot represent the true industrial value of the structure. Many coal docks and many blast-furnace plants depend so completely on continuous bridge service that they would be forced to curtail or abandon operations in case of a major wreck. The indirect losses sustained through loss of use and curtailment of dependent industrial operations, as in case of a blast furnace or steel plant, may easily be of greater magnitude than the direct and tangible losses.

That bridges do suffer severe damage from windstorms is convincingly proved by yearly records of losses sustained. In the period of 1920–1927, there were at least 27 complete or partial bridge wrecks; many around the Great Lakes. Between 1923 and 1928, inclusive, ten docks in Ohio, two in Illinois, and one in Minnesota suffered actual bridge losses aggregating approximately $1,375,000. A single storm, that of June 2, 1924, caused three losses in Ohio alone, totaling $465,000, and only eight days later, June 28, another storm in Ohio caused two additional losses amounting to $350,000. One dock at Lorain was struck by both storms with a loss of $75,000 in the first and $200,000 in the second. Other losses elsewhere in the United States and in Canada during the same period would greatly increase the above totals. These figures represent only the cost of rebuilding or replacing the wrecked structures. They do not include any of the indirect losses.

Windstorm damages or wrecks are caused in several ways. The most general cause of wrecks lies in the tendency for one end of the bridge to move faster than the other due to unequal

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

wind-pressure distribution and unequal driving and controlling forces. The bridge does not remain square with the runways, and eventually reaches a position where the runway rails fail or the legs supporting the truss twist and collapse. This is usually the result of movements of the bridge in the same direction that the wind travels. Unless the bridge is fitted with adequate modern-control equipment and safety devices, it is apt to be blown along the runways much faster than normal operating speeds; even with no power applied, and only the brakes released, most bridges will drift rapidly with the wind. Without adequate control and slowdown action, the application of brakes at such high speeds is almost certain to result in disastrous skids, since the brakes are usually effective enough to lock the wheels. This is especially true on wet or icy rails. Fig. 1 illustrates a bridge wrecked by lack of control and excessive skewage.

A bridge may be blown along the runways and crash into another bridge, with great damage to both. It may be blown along and crash into the runway bumpers with sufficient violence to overturn or collapse. In one case a bridge was wrecked by a wind striking it almost end on, while at a standstill. In this case, oscillations were set up which finally resulted in the failure of a poorly designed and defective runway, and a total collapse.

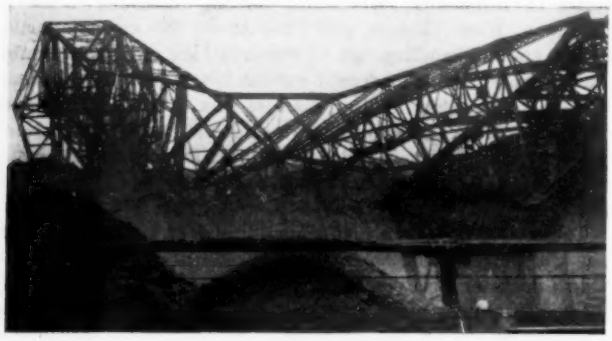

FIG. 1 WRECK OF RIGID-LEG, CABLE-HAULED BRIDGE AT CLEVELAND, OHIO, IN 1923

Storms of sufficient violence to twist bodily or overturn bridges are fortunately rare. It is very doubtful whether any movable bridge structure, however well fitted with safety devices, can successfully resist the direct force of a major tornado. The fluctuating currents and whirls result in tremendous alternating stresses; the enormous lifting power of the rotating center currents may conceivably lift the structure bodily and crash it down to a total collapse. The illustration, Fig. 2, shows a wreck apparently of this sort which has created a great deal of discussion. The portal-type pier leg and the truss were moved almost directly endwise into the vessel slip. There appears to have been almost no dragging of the trucks across the portal railroad tracks, with the exception of one broken rail. The bridge-runway rails themselves seem to be intact. The operator and another eye-witness to the wreck declared that the bridge seemed to rise and lurch through the air. This bridge had some rather large floor areas at the portal leg, and it is assumed that sufficient lifting force was exerted on these and other platform and cab areas to lift a large part of the 800 tons representing the weight of the bridge. Such lifting power is almost incredible, but competent observers and the evidence of the wreck itself point to that conclusion as being probably correct.

Winds of any intensity whatever are the result of difference in atmospheric pressure between two or more points on the earth's surface. These pressure variations may be local or may extend halfway across a continent, and are caused primarily by temperature differences at various points. The greater the pressure gradient, the more violent the atmospheric movement tending to equalize the pressure differences. In the northern hemisphere, a succession of high- and low-pressure areas travel from west to east. Alternate low- and high-pressure areas cross the United States with more or less regularity at the rate of about two per week. As a result of the earth's rotation, the inward movement of the atmosphere is not directly toward the center of the low-pressure area, but in a spiral counter-clockwise direction toward the center. Since the whole low-pressure

FIG. 2 SKEW-OPERATED, PORTAL-TYPE PIER LEG, MAN-TROLLEY BRIDGE, WRECKED BY TORNADO, SOUTH CHICAGO—1928

area is moving toward the east, the resultant wind velocities are generally much greater in the eastern and southern areas of this great circulatory movement. Such a movement is correctly defined as a "cyclone." The same term is often loosely and incorrectly applied to any violent storm, as a tornado, thunderstorm, or line squall. The term "cyclone" in its proper meaning does not refer to a destructive storm. The circulation of the atmosphere away from an area of relatively high pressure is spirally in a clockwise direction away from the center, and is properly termed an "anticyclone." The wind movement away from a high-pressure center is seldom as violent as the movement toward a low-pressure area.

Due to local differences in pressure, atmospheric disturbances of minor area, but often of extreme violence, are superimposed on the relatively harmless cyclone. Such storms are classed as thunderstorms, tornados, line squalls, etc. Local heating and cooling of the atmosphere result in violent horizontal and vertical movements of the air. Areas of heated air begin to rise and cold air from above flows down to replace it. The resultant changes in temperatures and pressures acting on air more or less saturated with water vapor result in snow, rain, or hail, sometimes accompanied by relatively undirectional, violently rotating windstorms. The violently rotating storm of small area and relatively short path is called a "tornado." Tornados are characterized by extremely great pressure drops at the center of the whirl, the whole spinning mass of air moving at a relatively slow speed along a path which does not usually exceed 40 or 50 miles in length. The rotating velocities in a tornado may exceed 200 m.p.h., and in conjunction with the very low pressure at the center are responsible for strange explosive and lifting actions. Nothing but the most massive structures can resist the forces existing in a major tornado.

The wind velocity in any storm is seldom even approximately constant. Continually recurring velocity changes and gusts occur, so that momentary stresses are imposed on wind-resistive

areas far greater than might be expected from a consideration of the ordinary weather-bureau velocity reports, which until very recently were invariably average velocities over one-, two-, or four-minute periods. Even now only a few prominent stations have apparatus capable of recording gust velocities. Fig. 3 is a reproduction of a velocity chart made with the Burton anemometer. The chart was run at high speed (each curved time division represents 15 sec.) so that the momentary variations and gust effects could be studied. Fig. 4 shows a section of a chart when operated at normal speed, each curved time line representing 15 min. This illustrates very well the extremely rapid velocity increase that characterizes many storms. The broad record band with its many peaks also graphically portrays the unsteadiness and gust phenomena of storms. Anemometers located quite close together often show wide differences in simultaneous wind velocities. For this reason, one anemometer cannot be expected to offer protection for a large group of bridges, nor can reports telephoned from a distant weather-bureau station have any local value.

Since the destructive energy of a storm varies approximately as the square of the wind velocity, the extreme importance of properly determining gust velocities in the protection of bridge structures is readily apparent. For safety, bridge-traversing movement must be discontinued when dangerous gust velocities are reached, without regard to average velocity determination.

Before proceeding to discuss safety in design and safety devices and attachments, a brief description of the principal elements of a modern material-handling bridge may be useful. Such a bridge in its essential form is made up of a steel truss structure supported on structural-steel legs which are equipped with multiple-wheel trucks for propelling the bridge along the dock runways. The truss may be of various standard forms such as the Howe, Warren, Pratt, and Catenary, riveted or pin connected. The supporting legs are usually of the pier and shear type, which names indicate fairly well their respective functions. The pier leg gives the truss lateral, longitudinal, and vertical support; the shear leg gives only lateral and vertical support, with little or no longitudinal stability.

The pier leg is usually either of "V" or portal type (also called "A" frame). The "V" type of pier leg resembles a skeletonized wedge, with the trucks and connecting sills representing the tip of the wedge and the broad upper end attached to and supporting the truss. This type of leg travels on a single rail or on two rails relatively close together. The portal-type leg may be like a square tower or more or less like the letter "A." This is supported on track-runway rails of very wide gages, 20 to 40 ft. or more, with two or three standard railroad tracks between them. This type usually has conditioning or screening apparatus built into it, and is equipped to load into railroad cars below. The shear leg, as its name would indicate, is simply a pair of structural legs or "shears" with a connecting sill and trucks at the lower end running on a single or double rails. The upper end supports the truss. The bridge truss may have cantilever extensions on one or both ends, or may have a folding "boom" extension at the slip end, which can be raised to clear the mast of boats; the trolley runs out on this extension when unloading the vessel.

Bridge construction may be further differentiated into "rigid" and "skew" types. Rigid bridges in general are those in which the pier and shear legs are rigidly attached to the truss, and are generally driven by horizontal and vertical shafting and spur and bevel gearing from one large motor located at some convenient point along the truss. Since both ends have a common drive motor, they presumably should travel at the same speed, and should keep square with the runways. Jaw clutches are commonly fitted in the horizontal drive shaft so that accidental minor "out-of-square" conditions can be corrected. The safety advantages and disadvantages will be discussed later.

The skew-type bridge, as its name would indicate, does not necessarily remain square with the runways. The trusses of

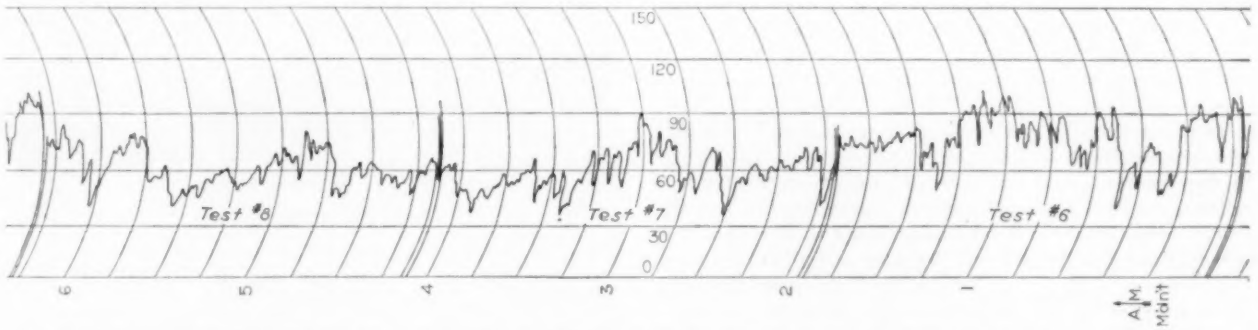

Fig. 3 Burton Anemometer Chart Showing Gust Variations in a Windstorm—Chart Run at High Speed—Each Time Division 15 Seconds

such bridges are supported on "skew" plates or turn tables on the tower or "V"-frame pier legs, centered by a king pin so as to permit horizontal rotation of the truss relative to the leg. Hanger eye bars, ball joints, or similar supports are provided for supporting the truss at the shear leg, usually also centered by a king pin or its equivalent. The two legs are equipped with single or multiple motors, with no shafting or other device for mechanical equalization of travel rates. Some bridges of this type may be operated as much as 40 or 50 ft. out of square with the runways. This flexibility has both operating and safety advantages and disadvantages which will be considered later. Fig. 5 illustrates skew-operated "V" pier-leg bridges, and Fig. 6 is a closer view of the "V" leg.

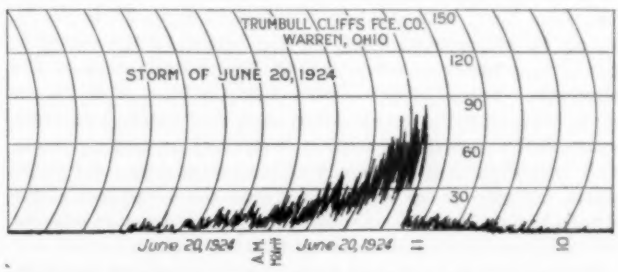

Fig. 4 Burton Anemometer Chart Run at Normal Speed—This Record Made at Warren, Ohio, at Time of Destructive Lorain Tornado, June, 1924

The hoisting and trolleying machinery proper has little

bearing on the protection of the bridge against storm hazards. Some bridges have rope-operated trolleys and hoists, with the motor and operating drives in a stationary machine house in the truss. The operator's or hoister's cab is also fixed, often in duplicate, so that either unloading from a vessel or working on stored material may be done to the best advantage. Practically all large modern bridges are of the man-trolley type, with the

FIG. 5 TWO SKEW-TYPE, V-FRAME, PIER-LEG, MAN-TROLLEY BRIDGES ON LAND STORAGE DOCK. MINNESOTA STEEL COMPANY, DULUTH, MINN.

hoist and trolley mechanisms supported in a movable carriage which also carries the control equipment and the operator, hence the name "man (riding) trolley." This arrangement is preferred because the operator moves with his load, has a better view of his work, and because this system eliminates the great lengths of wire rope and the multiplicity of sheaves and guides required by the rope trolley.

Many bridges are equipped with built-in or trailing car-loading and screening plants for properly preparing "run-of-pile" coal for domestic and industrial use. While these may add to the weight and stability of the bridge, they also add to the wind-resistive areas, so that they indirectly affect the safety of the structure under storm conditions. A trailing-type plant is shown in Fig. 7, attached to the shear leg of a rigid, shaft-driven bridge.

The actual forces exerted against the structural elements of a bridge are difficult to determine. The variety of rolled shapes and built-up sections employed, the varying angles of attack of the wind, the influence of mutual interferences of the eddies and gusts involved, all serve to complicate the problem. Large machine houses and enclosed cabs and screening plants all greatly increase the areas exposed to the wind. The general design of the bridge, therefore, has a considerable influence on its safety under storm conditions.

Good design demands a sufficiently broad wheel base to insure stability. Wind pressures are assumed at from 30 to 45 lb. per sq. ft. of projected area, and the heights of the center of gravity and center of pressure must bear proper ratios to the wheelbase. Recent bridges designed on the basis of 45 lb. per sq. ft. should prove exceptionally safe and stable. Machine houses in the truss should be kept as small as possible consistent with accessibility of the equipment they enclose. Screening plants, hoppers, or car loaders built into the lower part of the pier and shear legs add stabilizing weight and traction without adding disproportionately to wind-resistive areas.

Rigid, non-skew types of bridges with single- or multiple-motor drive, but shafted for simultaneous movement of the two ends, are often considered by their users to be safer in storms than skew-type bridges. It is claimed that they are easier to keep square with the runways, and that simultaneous starting and stopping are facilitated. There is probably smaller chance for controller failures or operator's mistakes to put the bridge into a hazardous position. On the other hand, due to the very rigidity of its construction, a breakage of the drive mechanism at one end, or a skid of one end on slippery or icy rails, may severely strain or damage the structure through its very lack of flexibility.

Skew-type bridges are intentionally made flexible enough to withstand large degrees of skew with relatively small hazard, but there is greater danger of excessive skews developing since either end travels independently of the other at a speed determined by the type of motors and control used, by the operator's manipulation of the controllers, by the driving or restraining force of the wind, by unequal friction losses in the drive mechanism, and by variable track conditions. Such bridges, for maximum safety in motion, must be equipped with properly designed controllers, motors, and brakes, and with auxiliary devices such as skew indicators, skew limit switches, and wind gages.

All bridges, whether rigid or skew operated, must have safe propelling equipment. All parts must be designed with ample

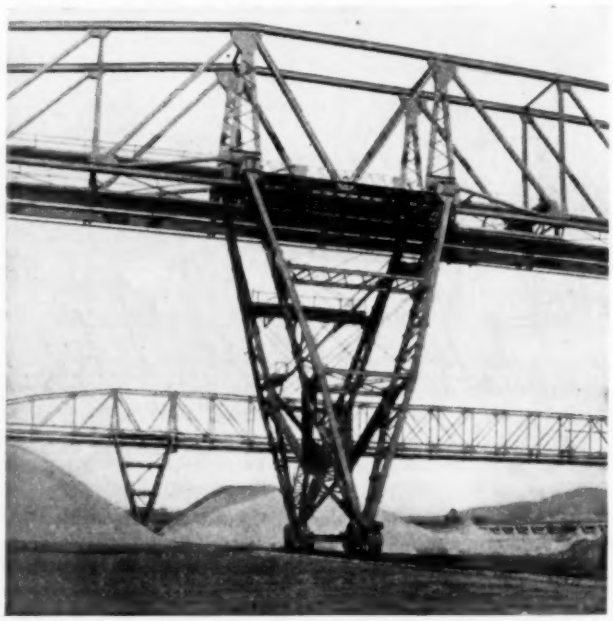

FIG. 6 V-FRAME PIER LEG, 100 PER CENT TRACTION DRIVE
(Same bridges as Fig. 5.)

factors of safety, and protected against accidental damage. Slow propelling speeds are highly desirable from a safety standpoint, though not so satisfactory from the operator's viewpoint, especially if frequent movements or long runs are necessary. Travel speeds range from 20 or 25 ft. per min. up to 150 ft. or more. Speeds of 20 to 50 ft. are very slow; from 50 to 80 ft. per min. is generally considered about right for most bridges. Propelling speeds over 80 ft. per min. are rather fast and require exceptional care and unusually good driving and braking equipment for maximum safety.

Bridges may be traction driven by the supporting wheels, either by a single motor shaft connected to part or all of the wheels, or by one or more motors at each end geared to part or all of the wheels, either end being free to move independently of the other. The mechanical drive may use bevel gears, spur-gear trains, worm gears, or various combinations of these. Flat-pitch worm gears are often considered advantageous on account of their so-called "self-locking" features against overhauling winds. Modern forms of worm gearing, however, are apt to be so efficient that too much dependence cannot be placed on their resistance to overhauling. The bridge of Fig. 7

is of the single-motor shaft-driven type with worm final drive, but only four of the ten bridge-supporting wheels at this leg are so driven. Fig. 8 illustrates another worm-driven bridge, but in this case all wheels are drivers, a pinion on each worm-wheel shaft meshing with two drive-wheel gears. Each four-wheel truck has its own motor. Fig. 6 shows a straight spur-gear drive to all supporting wheels. If wheel traction drive is used, maximum safety in motion and at rest demands that driving and braking effort be applied to 100 per cent of the supporting wheels.

Another method of moving the bridge along the runways is by means of cable haulage drums attached to the bridge trucks or sills. The cables are securely attached to the end of the runways, and make a number of traction wraps around the drums. Theoretically this may appear to be a safe drive, but in practice several wrecks have occurred which detract from its apparent safety. The cables must be kept tight enough to insure good frictional adhesion to the drum. The cables must be kept well oiled or doped to prevent rapid rusting and weakening. This weather-preservative treatment seriously reduces their adhesion to the drum, and encourages slipping. If two independent cables are used on each runway for each bridge, it is difficult properly to equalize the load carried on each, especially the braking loads. If several bridges operate on the same runways, each must have its own cable system, which in the aggregate requires considerable space and also increases the danger of fouling and other damage to the cables. The elasticity and

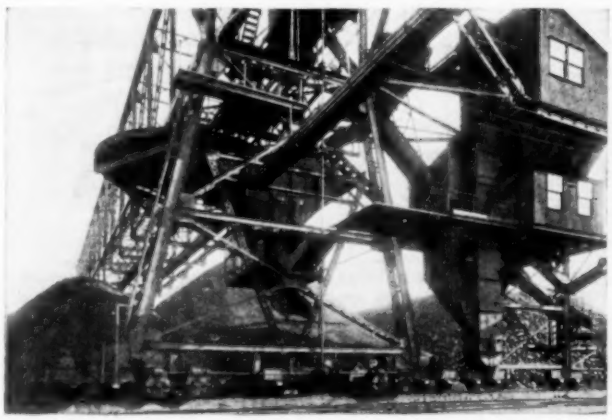

Fig. 7 Rigid-Type, Non-Skew, 40 Per Cent Worm-Driven Bridge. With Trailing Screening Plant—Note Automatic Rail Clamps. M. A. Hanna Coal & Dock Co., Superior, Wis.

"stretch" of cables on a long dock are also objectionable. This system is becoming obsolete; the author is not aware of any recent installation.

Both wheel and cable-drum traction systems of drive are subject to slippage, while in motion and on starting and stopping. As a means of avoiding such hazards, one of the prominent bridge-engineering companies is now engaged in modernizing seven old bridges at South Chicago by the installation of a rack-and-pinion system of drive. This system has been used on other bridges, and while it increases the dock cost, it undoubtedly provides a safer means of propulsion. A substantial rack is installed on each runway, into which are meshed two large-toothed drums or pinions. Each pinion has its individual driving motor, and all supporting wheels are idlers. All braking and driving loads are taken by the rack and pinion. Assuming that the drive mechanism is of ample strength and reliability, this method of propulsion provides the most positive control yet developed for bridges, even under severe storm and weather conditions.

However perfect the mechanical details of the driving mechanism, the selection of proper motor, control, and braking equipment is also essential. The propelling motors may be for either direct or alternating current. If for direct-current operation, the choice lies between series-, shunt-, and compound-wound motors. Alternating-current motors may be either squirrel-cage or wound-rotor construction.

Series motors are particularly well adapted for starting and running under heavy loads. The current-torque characteristic of such a motor is shown by curve (*a*) of Fig. 9. However, series motors have no inherently stable speed characteristic, and under light loads, excessive speeds may be attained. This condition exists when a bridge is moved in a strong following wind. Cutting in starting resistance has no appreciable slowdown effect if the wind is strong. The speed-torque characteristic is shown by curve (*a*) Fig. 10. This unstable speed char-

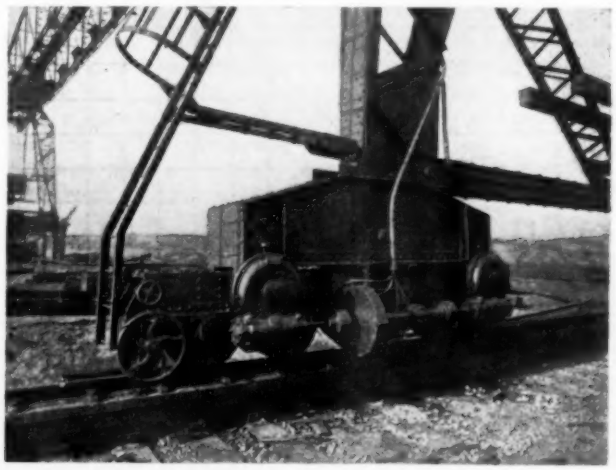

Fig. 8 Shear-Leg Truck Details—Worm Geared 100 Per Cent Traction Drive—Note Hand Wheel for Setting Manually Operated Rail Clamps

acteristic may be corrected by the use of a shunted armature connection, as shown in Fig. 11 (*b*), and a slow positive speed thus obtained under light loads as shown by curves (*b*) and (*c*) in Fig. 10. This connection also provides extremely effective electric braking in strong overhauling winds. Another advantage of series motors is that they divide the load equally when two or more motors are used on each end of a bridge.

Shunt-type motors, on the other hand, provide very stable and definite driving speeds, both under heavy and light loads and under severe overhauling wind conditions. The starting and heavy-load torque characteristics are, however, not as satisfactory as those of a series motor. Current-torque characteristics are shown by curve (*b*) of Fig. 9. The speed-torque curve is illustrated at (*d*) Fig. 10. The flatness of this curve indicates that unequal load distribution may be expected between two or more motors geared to the same load. The shunt motor can be run at reduced no-load speeds only by the use of armature-shunt circuits similar to those used with series motors. The slowdown action is not quite as effective, because there is no series field to be strengthened by the armature-shunt current. Series resistance in the armature circuit alone can reduce the travel speeds only with a positive load; as the load decreases, this speed rises to the normal no-load value, and rises still higher under overhauling conditions. As a matter of fact, in a strong following wind, the bridge will run faster on the starting points than with the controller full on.

The compound motor has some of the advantages as well as

disadvantages of both shunt and series motors. It has a better starting torque and a better current-torque characteristic curve than the shunt motor, but not quite as good as a series motor. It has a definite no-load speed determined by the shunt-field strength, but the no-load speed is considerably higher than at full load, and under following winds the bridge speeds are higher than with shunt motors. The current-torque curve (*c*) of Fig. 9 and the speed-torque curve (*e*) of Fig. 10 show its inter-

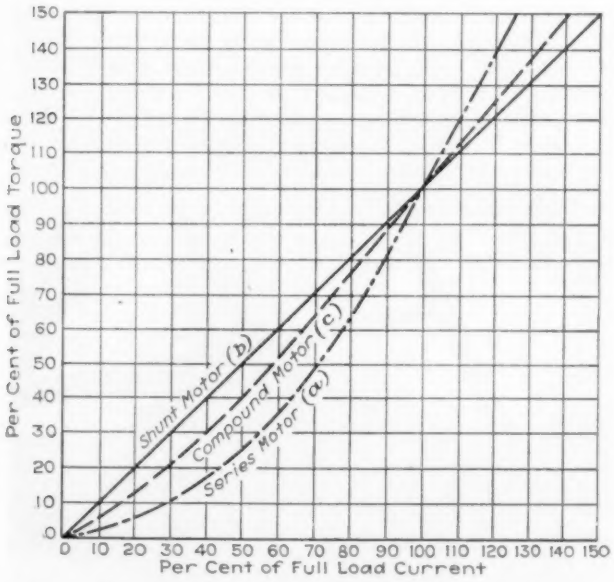

FIG. 9 CURRENT-TORQUE CHARACTERISTICS OF D.C. MOTORS

mediate characteristics. This motor may also be used with an armature shunt more effectively than with the shunt motor, not so well as with the series motor. The division of load between two motors on the same drive is also better than with the shunt motor.

The series motor is most generally used as a bridge-propelling motor, because of its desirable heavy-load characteristics and because by the use of armature shunts it can so readily insure the slow creeping speeds that are necessary in making smooth stops

Alternating-current motors for bridge drive are generally three-phase induction type, with either squirrel-cage or wound rotors. The large motor used on single-motor shaft-driven bridges is almost certain to be of the wound-rotor or slip-ring type, since it has much better torque characteristics at heavy loads. Multiple motor drives are preferably of rotor-wound type also, because of better performance, though squirrel-cage motors might be used. Induction motors have limiting no-load speeds a little higher than full-load speeds. Strong overhauling action of following winds causes the speed to rise only a little, accompanied by a regenerative-braking action. Unless an auxiliary supply of direct current is available, slow down or dynamic braking points are not practicable, with induction motors.

While many bridges have been built for alternating-current operation, the modern trend seems to be toward the use of direct-current power supply at 250 to 600 volts, derived from a dock substation. The characteristics of direct-current series motors which make them valuable for bridge-propelling drive also make them more suitable for hoist and trolley, as well as for boom hoists and other bridge auxiliaries. Screening plants may be considered an exception to this, because the loads are fairly steady and the absence of commutator and brushes is an advantage of the alternating-current motor.

It seems scarcely necessary to suggest that only weatherproof totally enclosed motors of heavy-duty type should be used for multiple-motor drives, where the motors are mounted directly on the trucks. Single-motor drives are usually provided with a roomy enclosure, which frequently houses other machinery, and these motors do not need to be totally enclosed or weather-proof.

Perhaps equally as important as the correct choice of driving motors is the selection of proper control equipment. Desirable features of a good control system include the following points: smooth starting and acceleration, moderate speeds in strong overhauling winds, powerful slowdown operating points to be used for stopping, and have suitable overload and no-power protective features. Slowdown speeds 20 per cent to 30 per cent of normal full-load speeds will permit smooth application of the brakes with little shock or jar.

Manually operated drum-type or face-plate controllers are no longer considered desirable. Unless the operator is par-

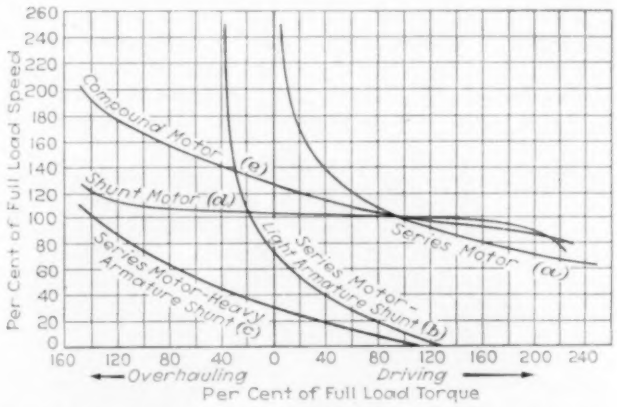

FIG. 10 SPEED-TORQUE CHARACTERISTICS OF D.C. MOTORS—ALSO SHOWING EFFECT OF ARMATURE SHUNT CONNECTIONS

ticularly careful, they do not give smooth acceleration, and the fact that they usually do nothing more than notch back starting resistance in stopping means that they are not apt to slow the bridge down before it is stopped by the brakes. Manual controllers may be equipped with "armature-shunt" slow down points, which greatly improve their action, but many of the good features of magnetic controllers are lacking.

Modern magnetic controllers provide for uniform acceleration to full speed without undue shock or jerking. They also provide under-voltage and overload protection, and should be arranged so that after a power failure the controller must be centered before movement can again be resumed. This is necessary to prevent a bridge from starting up and running away in case the controller should be left "on" and the operator leaves his post. This particular protective feature may also be obtained by the use of platform or dead-man switches, on which the operator must stand while the bridge is in motion. Such platform switches ought to be so designed that a lazy operator cannot render them inoperative by blocking or weighting them down. Spring-centered master controllers are also useful, since they must be forcibly held in the operating position, and return to center if released. A desirable feature of some controllers is a low-torque first operating point, designed to take up the slack in the drive gearing without positively starting the bridge in motion. Secondary points provide for slow (armature-shunt) operation, and then acceleration controlled by current

or timing relays to full speed. Sometimes more than one point of slowdown operation is provided so the graduated slowdown action similar to the accelerating points can be obtained. The maximum slowdown point should positively provide a very slow final speed before power is cut off the drive motors and the brakes are applied.

Keeping the bridge square or within certain reasonable degrees of skew is one of the most important functions of a good magnetic-switch controller. Skew limit-switch arrangements, which may be simple or elaborate in construction and operation, are a positive necessity on skew-operated bridges.

The older types of limit switches were arranged so that they merely cut power off the bridge whenever the skewage exceeded a fixed amount. Generally the correcting circuits were not affected, so that by reversing the controllers the bridge could be squared up and the limit switch automatically reset ready for forward movement again. Improved types of limit switches have graduated control, first slowing down the leading end by series resistance, and then armature-shunt operation, giving the lagging end a chance to catch up. If it gained on the leader, full-speed operation would again be resumed. Should the slowdown action be insufficient and the skewage still increased,

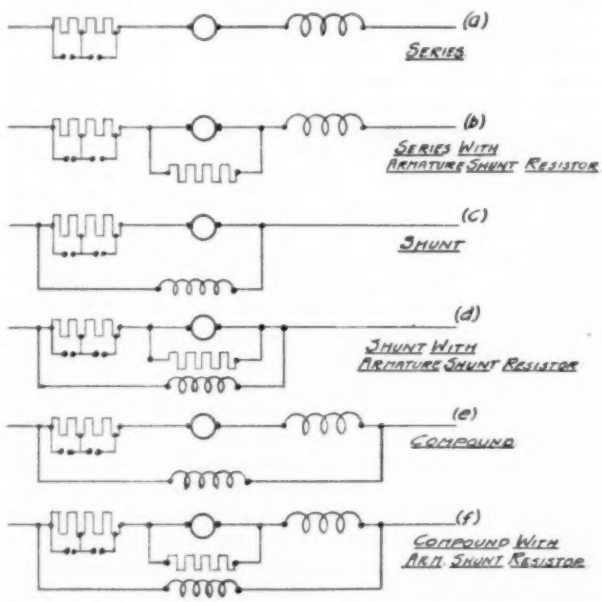

FIG. 11 ELEMENTARY CIRCUITS, DIRECT-CURRENT MOTORS

a final limit point was reached at which both ends were stopped, and movement could be had only in the corrective directions.

Still more elaborate and effective systems of skew control are in use. One form developed and patented by the author and used on a number of bridges, operates as indicated in the following brief description:

The special magnetic-switch contactor board controls both ends of the bridge, subject to the manipulation of two master controllers and a special multiple-point skew limit switch. The two ends of the bridge may be moved simultaneously or independently either in the same or opposite directions, either at slow armature-shunt speeds or automatically accelerated to full speed at the will of the operator, as long as the bridge remains in the normal "center" zone of skewage. As soon as this degree of skew is exceeded, the leading end is automatically slowed down, and the lagging end either maintained at or brought up to full speed. If for any reason the two ends are moved in opposite directions, both ends slow down, but continue to move. If the slowdown action is still insufficient to correct the skew, a point is reached where the leading end stops, while the laggard end still continues at full speed. At the same time that this action takes place (through the operation of the skew limit switch), circuits are established whereby all control by the operator is eliminated, and the bridge squares itself up and stops. Stopping is accomplished by armature-shunt action, then a no-power dynamic-braking circuit is established as the power is cut off and the brakes are applied. After the automatic squaring action is instituted no manipulation of the controller by an excited operator has any effect until the bridge has stopped and both controllers are centered preparatory to a fresh start. The underlying aim and intention is to keep the bridge square as long as possible under any unusual load or wind condition; if certain limits are still exceeded, then to make squaring up and stopping fully automatic and non-interferable by the operator.

For bringing the bridge to a complete stop, and for preventing the rotation of the drive mechanism even under heavy winds, some form of brake operating on the armature shaft or some part of the drive mechanism is absolutely essential. These may be operated by magnets or solenoids, by compressed-air cylinders, or by mechanical devices. Electrically operated brakes are used in practically all cases, so connected that they are released by power circuits established as the operating controller is moved to the running points, and set at once when the controller is centered or the power supply is interrupted. These brakes may take the form of wheels on the armature shaft, with friction bands or shoes set by gravity or powerful springs and released by a solenoid. Other brakes are of disk type in which alternate disks are keyed to the armature shaft and to the brake case, and pressed together on application of heavy springs. To be effective, the brakes must, of course, be fully weatherproof or properly housed. They should release quickly and completely, and should set smoothly, but without grabbing or sudden locking, yet hold so securely as positively to prevent rotation of the drive mechanism even under great wind pressures.

As mentioned under the discussion of controllers, it is also highly desirable that slowdown control points be provided, so that the brakes do not have to absorb all the energy of the moving bridge. In some cases, timing relays or dashpots have been used to secure graduated application of the brakes, but these should not be necessary if good slowdown action is provided. If the bridge does not have 100 per cent drive, it is quite desirable to have groups of idler wheels geared together and locked by effective brakes. One hundred per cent braking is particularly desirable in stormy weather.

In order to increase the safety of slowdown points and holding brakes, some bridges are equipped with track sanding devices. These may be air or electrically operated, and should be electrically heated to keep the sand dry and free from clogging or caking. The sand used must be screened carefully so that lumps or pebbles do not foul the sand valves. The sand pipes should discharge the sand as near the wheels as possible. If sanders are kept filled and in good order, they are valuable aids in making safe stops. In some cases, they have been interconnected with the travel controllers, so that on the slowdown points sand is automatically fed to the rails.

Some form of skew indicator should be installed on every bridge that is even slightly skew operated. Under certain conditions, an operator might be able to estimate the degree of skew without an indicator, but under storm conditions or at night such estimation would be too hazardous. Skew indicators usually take the form of a graduated arc or dial, over which a mechanically operated pointer or hand moves as the bridge is skewed. The indicator, of course, should be mounted so as to be

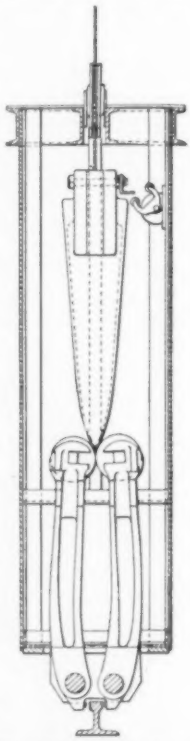
plainly visible to the operator as he stands at the travel controllers.

So far, the equipment considered has been concerned principally with the propulsion of the bridge. A class of devices must now be considered, which from the standpoint of bridge protection against windstorm hazards are unquestionably of superlative importance. This group of devices includes manual and automatic rail clamps, manual and automatic wheel chocks and wedges, safety struts, sprags, spuds, and mooring cables, all of which are designed for the sole purpose of immovably anchoring the bridge. Some of these devices are released each time the bridge is moved, and reengage immediately when the bridge movement is stopped, either by the controllers or because of power failure. Others are intended to be used only in the

FIG. 12 EARLY-TYPE, MANUALLY OPERATED, SELF-TIGHTENING RAIL CLAMP—MEAD-MORRISON MANUFACTURING COMPANY

event of an approaching storm, or in case the bridge is to be idle for some time, as between shifts or overnight.

Rail clamps are devices for gripping the head of the rail powerfully, so as frictionally to increase the resistance of the bridge against wind forces. Originally, they were all hand operated, with relatively limited holding power. Some were of plain vise construction, with smooth or roughened jaws. Others had self-tightening features which increased the restraining ability when the bridge moved slightly. One of the earliest self-locking clamps is shown in Fig. 12. This was initially applied by the action of the toggle links and two traveling nuts, and had self-tightening cams which tended to hold tighter as the force against the clamp increased. However, bridge structures are large and movements are so frequent that it is physically impossible to set such clamps every time the bridge is moved. They require considerable time to apply, and in a sudden storm it would be hard to get them tightened quick enough. Manual clamps of various sorts are still used as auxiliary locking devices, but power-operated clamps are now almost universally used, and are much more powerful and effective than hand clamps.



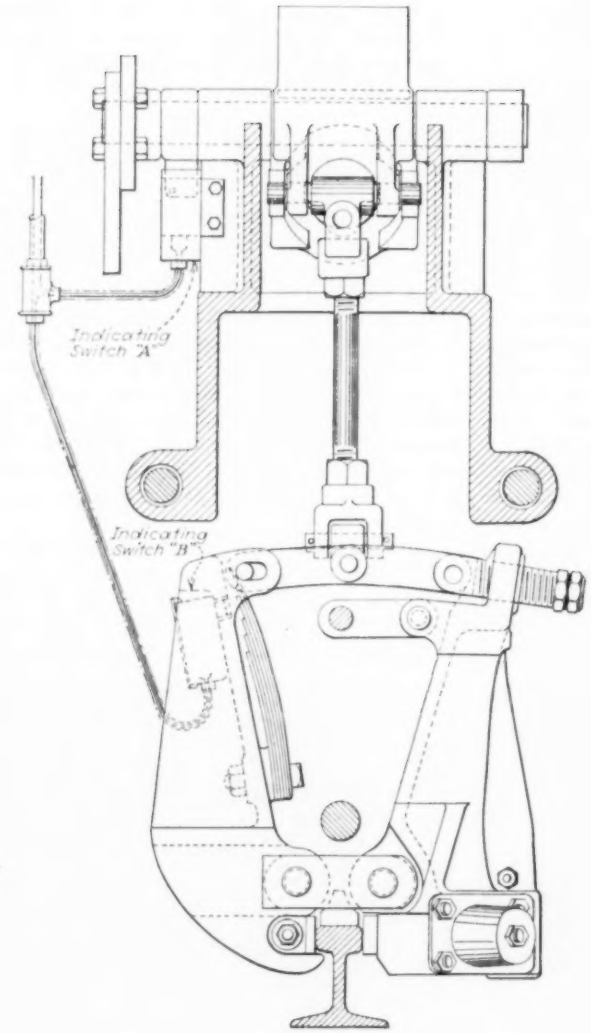


FIG. 13 GRAVITY-SET, DIRECT-PRESSURE, AUTOMATIC RAIL CLAMP—HEYL & PATTERSON, INC.

All modern automatic rail clamps are arranged so that they are released by some power-operated device (winch or a compressed-air cylinder), and are set independently of any power circuit by means of gravity operation of heavy weights or by powerful springs. Fig. 13 illustrates a very powerful direct-acting clamp using serrated and hardened replaceable gripping shoes. These are released by a motor-operated winch and cable system which hoists the wedge-shaped weight, the jaws being released by a spring. The weight is held up by stalling the winch motor through a bank of resistance, or by a power-applied brake on the winch-motor shaft, as long as the bridge is in motion. As soon as the travel controller is centered or the operator steps off a platform switch, or power fails, the weight descends, wedging the roller-equipped levers apart and exerting a powerful grip on the head of the rail.

Another type illustrated in Fig. 14 is the modern development of the manual clamps shown in Fig. 12. This is released by a motor-operated winch, held released by a shunt-operated solenoid brake, and set either by a weighted lever or a powerful spring. This clamp does not depend for its holding ability on the sole action of the weight or spring. These supply only the initial force of application. As the bridge starts to move, the circular cam with its double-tapered wearing shoe immediately rocks over, and creates a tremendous locking pressure that increases as the force against the bridge is increased. The arrangement of the gripping shoes and cams is shown in the upper corner of Fig. 14. As soon as the clamp is released, centering springs return the cam to its normal position. These clamps are claimed to have a restraining ability of 40 tons for a single rail clamp or 80 tons for a double clamp. Present models of these clamps are built with telltale switch devices attached, so that the lighting of a signal lamp shows when they are in proper adjustment and corrrectly applied. Fig. 15 shows one of these double rail clamps built into the sill of a bridge. This cut also shows a sander and the sand pipes in front of the wheels.

Fig. 17 illustrates another type of self-locking clamp which creates a very effective grip on the rail by means of a cramping or jamming action. Two levers, one free to move toward and along the rail, and the other fixed longitudinally, but free to

CLAMP APPLIED

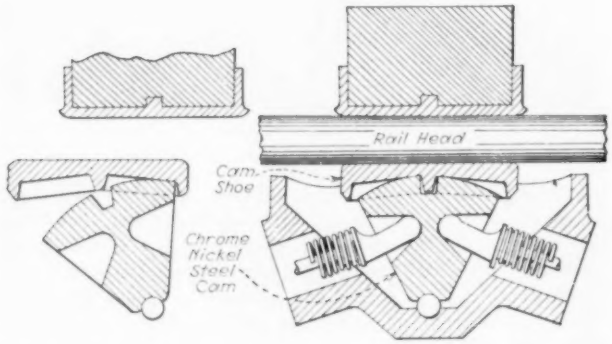

FIG. 14 SPRING-OPERATED, SELF-LOCKING, CAM-TYPE, AUTOMATIC RAIL CLAMP—NOTE TELL-TALE SWITCHES FOR INDICATING PROPER FUNCTIONING

move toward the rail, are connected by a heavy T-bolt. A weighted wedge behind the head of the T-bolt forces the levers into contact with rails, and any motion causes a cramping or jamming action which is very effective. Other forms of effective clamps are in use, but need not be described here.

A recently developed automatic locking device is shown in Fig. 16. This takes the form of an automatic power-operated wedge or wheel chock. While the bridge is in motion, this device is suspended on links clear of the rail, being released by a motor-operated system of pull rods and cranks. When power is cut off, a magnetic clutch is released allowing the wedge mechanism to drop down to the rail, under control of adjustable fluid-filled dash pots, and rests directly in front of the track wheel. A heavy weight and a system of toggles causes the wedge to be clamped solidly to the rail head. If the bridge moves a very short distance, the wheel moves up onto the point of the wedge, and under continued movement the face of the wheel bears against the curved surface of the chock, effectively blocking it. The grip arms are required to hold the device only against slipping until the wheel rides up on the wedge, after that the whole load on that particular wheel is effective in keeping the chock from slipping. The time of release is very short, and therefore delays bridge movement very little. The restraining force is developed directly against the truck, and heavy sill members are therefore not required.

All of these automatic-locking devices are intended to be set all the time the bridge is stationary, and should be released only when the bridge is to be moved. They are generally controlled by a platform or treadle switch on which the operator must stand to manipulate the traverse controllers. The instant he steps off of the platform or the power supply fails, the clamps or wedges begin to set; they should be invariable interlocked with the travel-motor contactors so that power cannot be applied to the motors until the clamps are fully released, and so that it is impossible to set the clamps without cutting power off the motors.

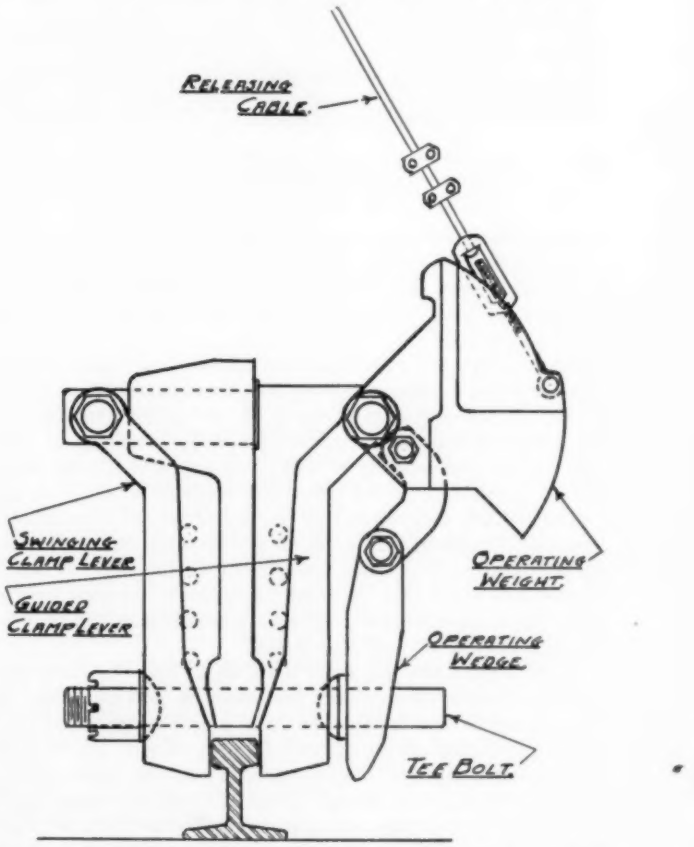

FIG. 15 JAMMING-TYPE AUTOMATIC RAIL CLAMP—INDUSTRIAL BROWN HOIST CORPORATION

Sufficient time must elapse in setting such clamps or wedges so that brakes have time to stop the bridge. For test purposes, a cut-out or short-circuiting switch is sometimes installed, so that routine tests of the holding power of the clamps can be made conveniently, by leaving the clamps set and energizing the motors. If they are in proper operating condition, they should resist the movement of the bridge under full-load current. Such periodical tests are essential in maintaining the clamps at maximum effectiveness.

When the bridge is to be idle for a considerable length of time, between shifts or overnight, or on evident approach of a storm, many dock operators supplement the automatic devices just described by other manually operated equipment. Manually applied rail clamps may be used; hardwood wedges about 18 in. or 2 ft. long may be placed under a number of the supporting wheels. Should the bridge move, the wheels will run up on these

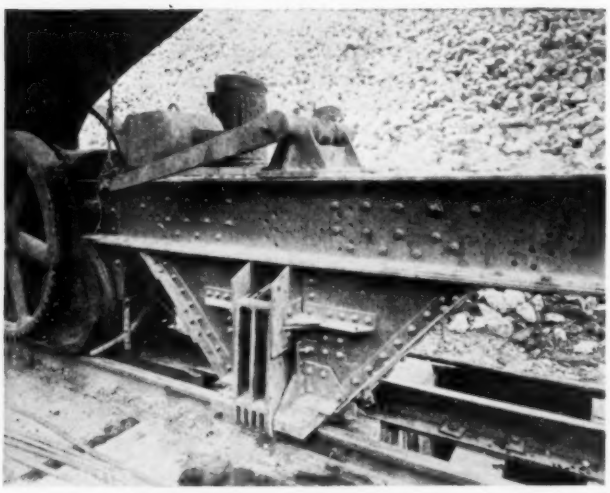

FIG. 16 GRAVITY-OPERATED, CAM-TYPE, AUTOMATIC CLAMP BUILT INTO BRIDGE SILL
(Note also track sander and sand-delivery pipes under track wheels.)

wedges, which really are very effective in blocking further movement. A very desirable arrangement is to have these wedges fitted with chains and to supply hooks on which to hang them when not in use. If loose they are apt to be lost or used for other purposes.

Struts or sprags of various sorts are used on many bridges. In some cases, these are built-up structural beams substantially pivoted at one end to the bridge truck, and pointed at the other end, with the hope and expectation that in an emergency they will dig into the concrete or timber runway and thereby block further movement. Other struts are similarly attached to the trucks, but are designed to grip the ball of the rail by manually tightened clamps or shoes. Their effectiveness depends largely on the degree of frictional attachment to the rail. If heavy enough and fitted with setscrews or hardened serrated inserts, they may be quite effective. They are usually arranged to make an angle of 30 to 40 deg. with the rail.

A much more effective strut is shown in Fig. 17. These are of much heavier construction, are seated in pockets formed in the monolithic foundation, and have a jack-screw adjustment so that they may be set up very tightly. These require more careful spotting of the bridge in order to reach the track pockets which are installed at regular intervals along the whole length of the runway, but they are much more effective than the other types of struts. When the bridge is in motion, all such struts are held up out of the way by counterweights or latches of some sort.

Another locking device takes the form of a heavy vertical structural spud or plunger, which may be raised or lowered by a hand wheel, and drops into sockets in the track foundations. While these require accurate spotting, they are very effective in preventing movement.

Some bridges are fitted with mooring cables intended both to anchor the bridge and to stabilize it against overturning forces. The cables are attached to the track by bolts and clevises or clamps, and generally run over a sheave high up on the leg and thence down to a hand-operated winch for tightening them. In some cases, the upper end is simply wrapped and tied around bridge members, and anchored in the nearest available hole, not being tightened. In most cases, the cable is not much larger than about $^{3}/_{4}$-in. plow steel, and the possible restraining force when extended at the customary angle of about 45 deg. is relatively very small when compared to the wind thrusts that often occur. Larger cables would be more effective, but too stiff and heavy to handle. The exposed condition of the cables leads to their rapid deterioration and short life. In many cases, the cables are poorly attached to the track or the bridge, so their value is extremely limited.

The physical condition of the track rails has an important bearing on safety in windstorms. This is particularly true with respect to fins and beads on the ball of the rail caused by the rolling action of the wheels. Beaded rails seriously limit the effectiveness of most forms of rail clamps, and it is very necessary

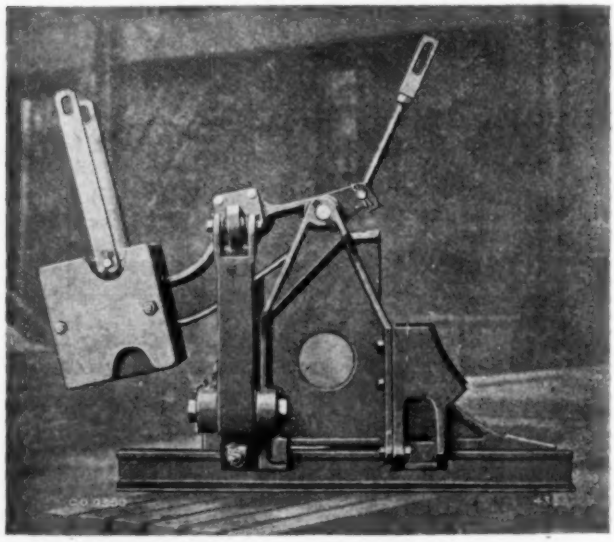

FIG. 17 AUTOMATIC-WEDGE OR WHEEL-CHOCK SAFETY STOP—WELLMAN ENGINEERING CORPORATION

that such beads be kept ground, chipped, or planed off. Some bridge trucks have been fitted with tool holders so that beads may be planed as the bridge runs along the rail. Other planing devices are intended to be dragged along the track by the bridge. Cutting tools may be shaped and adjusted to form a fairly large radius, which tends to lengthen the time before it is necessary to repeat the operation.

To insure safe anchorage of the bridge by automatic locking devices, it is necessary that the track rails themselves have good support. Most modern docks have monolithic concrete runway foundation; if on "made" ground or waterfront docks, it is necessary to support the foundation on piling. The rails should not be supported directly on the concrete, but on heavy longitudinal or transverse steel plates, or in some cases on treated ties or timbers embedded in the concrete. Rails bearing di-

rectly on the foundation tend to cut and wear into the concrete, resulting in loose rails, bad joints, and breakages. Anchor bolts must be amply strong, deeply anchored, and large enough to discount weathering and corrosion. Some dock operators make it a point to oil or paint the threads and replace the nuts at regular intervals. The rail joints must be well bolted, though the use of improved forms of splice bars may be impossible due to interference with some types of clamping devices. The top of the foundation should be sloped properly for drainage. If the rails are laid double on close centers, slots must be provided to prevent water from filling up the space between the rails and freezing. The rails and foundation must be kept clean and clear of lumps of coal, ore, stone, etc., which might cause derailment or might damage or destroy the rail clamps.

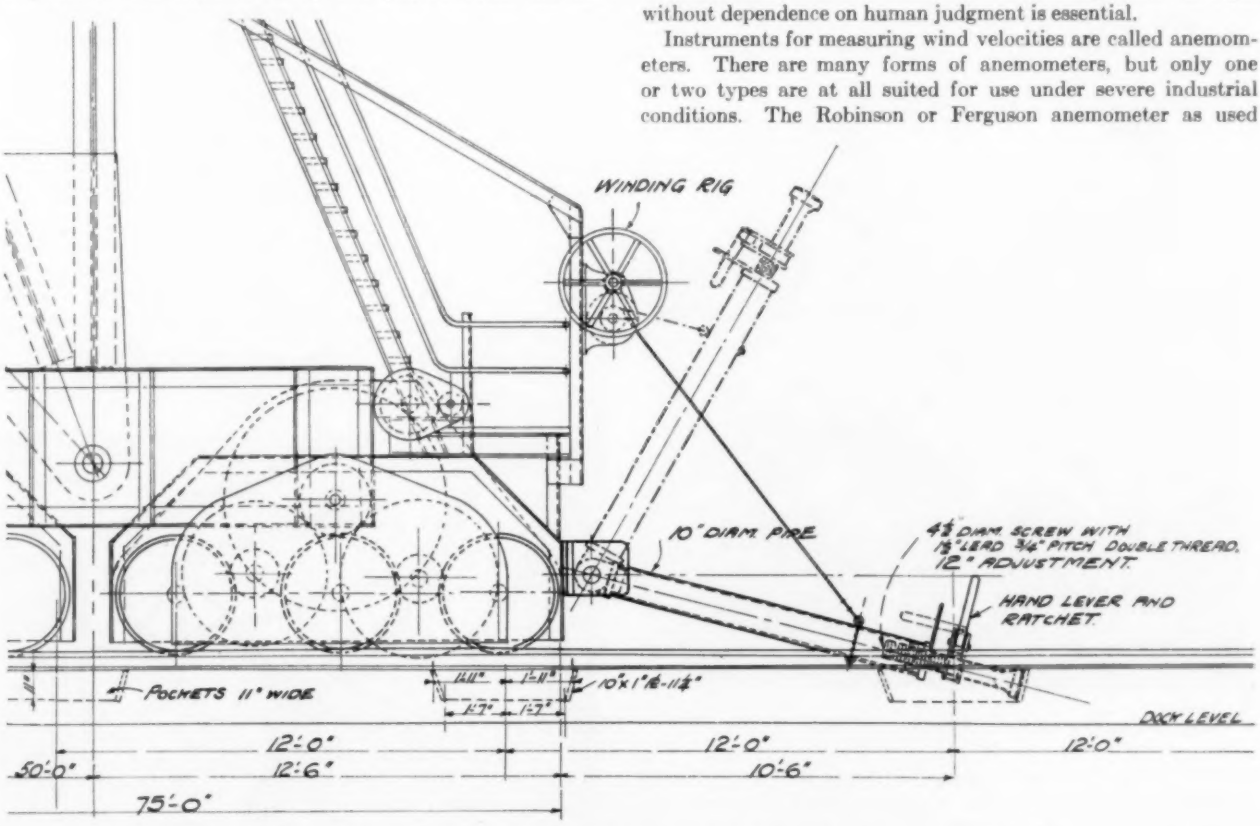

FIG. 18 HEAVY-DUTY, ADJUSTABLE SAFETY STRUT—NORTH WESTERN FUEL CO., SUPERIOR, WIS.

The ends of the track runways should be fitted with substantial and properly designed bumpers to prevent the bridge from running off the end and overturning. Bumper design preferably should be such as to prevent extremely abrupt stopping of the bridge. Gradually increasing slopes or rails bent vertically into a radius larger than the wheels and substantially supported are desirable; the lifting effect helps to counteract the overturning moment. Even a heap of earth or a timber or tie cribwork backed up by earth on top of the runway in the absence of regular bumpers may slow down and stop the bridge. Naturally, if inadequate control equipment is used, and the bridge is driven at high speed by the wind and crashes into any sort of bumpers, the result is very apt to be a serious wreck. The arrangement and design of the truck members themselves often limit the safety and effectiveness of any sort of bumpers.

The foregoing discussion has attempted to cover the factors of bridge design and equipment which have a more or less definite bearing on the ability of the bridge to withstand storms successfully. If the bridge is well designed and fitted with a full complement of adequate protective equipment, the probability of loss is remote. But how are dangerous storm conditions to be recognized? Upon what basis shall the operator or dock foreman decide to discontinue traversing movements? The vessel must be unloaded; the waiting cars must be loaded; who is to be responsible for delays, or who is to be blamed for a wreck? Of what value are elaborate systems of brakes and rail clamps, wedges, and struts, if they are not used in time? A consistent and accurate means of determining wind strength without dependence on human judgment is essential.

Instruments for measuring wind velocities are called anemometers. There are many forms of anemometers, but only one or two types are at all suited for use under severe industrial conditions. The Robinson or Ferguson anemometer as used by the Weather Bureau furnishes only average velocities, while wind-resistant structures require peak and gust protection. Pitot- or venturi-tube anemometers might be used, but they are unsuitable for long-distance operation or making permanent records. The indicating instrument is delicate and may easily become deranged. The tube openings are almost certain to clog with ice and snow during the winter months. Direct-pressure plate anemometers are simple and at first thought might be considered well adapted to bridge protection. However, they are apt to freeze up; snow and sleet loadings change their calibration. They are almost useless for distance observation, and do not make permanent records. Gust conditions set up pendulum-like oscillations, resulting in false indications. The constant oscillation likewise is destructive to contact-making devices which may be fitted for distance operation of signal devices. The chief merits of this type of wind gage are its simplicity and low cost.

For accurate and reliable industrial determination of wind strength, the revolving cup-wheel magneto-generator type of anemometer seems to be the most successful. This consists

of a three- or four-arm spider, on the spokes of which are mounted hollow hemispherical or parabolic cups. The cups all face the same direction relative to the imaginary "rim" of the wheel, and the assembly is mounted on the vertical shaft of a magneto generator, so that the cup wheel revolves in a horizontal plane. This mounting is non-directional and requires no vanes or tails to keep it headed into the wind. The generator is fitted with permanent-magnet fields, so that the generated voltage is proportional to the rotative speed. Fig. 18 illustrates the component parts of this type of generator and Fig. 19 its installation on a bridge. The armature revolves on high-grade ball bearings, the weight of the moving parts is small, and the large driving cup-wheel assembly is powerful enough to render the effects of

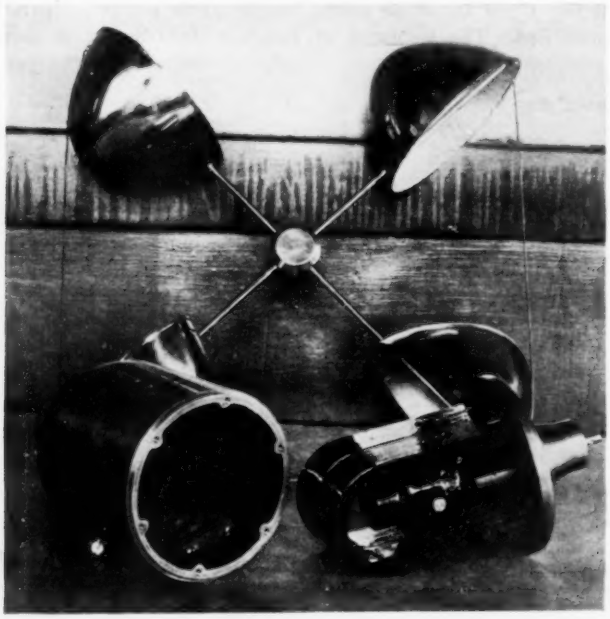

FIG. 19 CONSTRUCTIONAL DETAIL OF BURTON ANEMOMETER

bearing and brush friction negligible except at the very lowest velocities, which are of little industrial importance any way.

An anemometer of this type is especially suited for bridge protection. The generator is simple, rugged, weatherproof, and requires very little care or attention. The generator may be mounted at any suitably exposed point on the bridge, and is connected by two small wires to an indicating or recording meter, which may be located where most convenient for observation. It is equally well adapted for operating a distance of $^1/_2$ mile or more as for 50 ft. Either indicating or recording instruments may be used. It is sometimes desirable to use both, mounting the indicator directly in front of the travel controllers where it is most readily seen by the operator when he wants to move the bridge. The indicator requires little room and its readings are plain and understandable. The recording meter requires more room and other locations may be more convenient. A permanent record of wind velocity is made, showing the general trend of the storm. The fact that a permanent record is being made for the superintendent's inspection has a tendency to enforce cautious operating practices.

But suppose the operator ignores and disregards the indicating meter or recorder? How is his rash judgment to be curbed? For this purpose, a relay system has been developed, which is designed to prevent such carelessness. The relay panel carries an adjustable relay connected to the anemometer generator, and the relay in turn controls a small power contactor on the same panel. Signal devices such as lamps or sirens are controlled by this contactor, and in addition it may be connected into rail-clamp or travel-controller circuits so that continued movement is impossible in high winds. If the bridge is idle, the clamps cannot be released; if in motion, it is stopped. This means that the bridge will always be stationary and anchored the moment the wind exceeds whatever velocity has been chosen as the limit for a safe operation. If the bridge is thus stopped before the wind has a chance to reach a destructive velocity, and the bridge is promptly anchored to the runway, the possibility of runaways and wrecks are minimized. The whole secret of safe control lies in the prompt automatic enforcement of safe-operating practices. There is no opportunity or incentive for the operator to risk a hazardous movement.

Auxiliary recording pens are often fitted to the recorder and connected so as to record additional functions or details of operation. For instance, the time, duration, and direction of bridge movement may be recorded accurately, so synchronized with the velocity record that the concurrent operating condition can be determined readily. The proper functioning of the rail clamps may be made a part of the record, and any lack of adjustment or blocking of platform-switch or clamp mechanisms may be detected. Sometimes a record of wind direction is considered desirable. By using a suitable contact-making wind vane and a set of direction pens writing on the velocity chart, this record can be obtained readily.

FIG. 20 BURTON ANEMOMETER GENERATOR ON COAL BRIDGE

Sometimes dock operators object to having bridge movement forcibly discontinued while the wind strikes the bridge nearly "end on." Such end winds do not create propelling forces and are relatively safe for bridge movement. A wind vane may be arranged for selective control of the anemometer relay so that in certain "end zones" the relay-tripping velocity may be considerably increased, or automatic relay action may be eliminated entirely. In either case, full automatic control is resumed the instant the wind swings into the hazardous side directions.

Watchman service is also important in the protection of the bridges. Regular inspection should be provided at stated intervals between shifts and at night or other times when the equipment is idle, with definite instructions relative to the checking of manual and automatic safety devices. Regularity of inspections should be checked by a watchman's recording clock, with key stations at each end of each bridge. Written reports on special forms covering all protective features should be sent to the superintendent daily.

The complete bridge structure including all automatic and manual protective devices should be rigidly inspected at least twice a year by a competent inspecting engineer, preferably not connected with the regular dock-operating organization. Such inspections are a regular part of most insurance services and maintenance agreements. All valid recommendations by such inspectors should receive prompt attention.

Having considered the causes of windstorm wrecks and the devices designed to prevent such losses, in conclusion a tentative set of specifications may be framed, which if adhered to ought to afford the maximum degree of protection against storm hazards. The specifications are considered from three definite angles: (1) Safety while in motion, (2) safety while at rest, but with bridge in regular operation, and (3) safety while at rest during idle periods.

Safety While in Motion

1 The bridge builder must make ample allowance in his design for wind pressures of 40 to 50 lb. per sq. ft. of projected area.

2 The bridge must have a safe ratio of height of center of gravity and center of pressure to wheelbase.

3 The bridge should be 100 per cent traction driven or rack-and-pinion propelled; in either case with multiple motors and duplicate drive mechanisms at each leg.

4 The bridge should have smooth, powerful brakes, locking 100 per cent of the supporting wheels or all rack pinions. Graduated or retarded brake setting may be desirable, unless effective slowdown control is used.

5 Propelling motors should have inherent constant-speed characteristics, or the control system should provide such constant-speed notches. If direct-current series motors are used, one or more points of powerful armature-shunt slowdown should be provided.

6 Skew limit switches must be provided, preferably of types which afford graduated slowdown or full-automatic skew correction.

7 The operating master controller should be self centered, or have a platform or dead-man switch for controlling bridge-travel power.

8 Controllers should provide overload and no-voltage protection, and be interlocked with rail clamps or wedges so that power cannot be applied until they are released.

9 Accurate skew indicators should be plainly visible to the operator.

10 A reliable anemometer should at all times show gust and peak velocities, and also operate signal devices or cut power off in dangerous winds; as soon as power is cut off, brakes must be applied and setting of clamp devices initiated.

11 All parts of controllers and drive mechanisms should be kept in first-class condition, and runways kept tight and clean.

12 Adequate lighting for night operation should be furnished.

Safety at Rest During Normal Operation

1 The supporting wheels should be locked 100 per cent by effective brakes, or all pinions of rack-and-pinion drive systems should be locked.

2 Effective automatic clamps or track wedges must be applied at all times when the bridge is not in motion, operating on rails maintained in good condition.

3 An anemometer should prevent release of rail clamps or wedges if the wind exceeds a set danger velocity, usually 35 to 40 m.p.h.

Safety at Rest During Prolonged Idle Periods

1 In addition to automatic brakes, clamps, wedges, and struts should be furnished seated in foundation pockets or

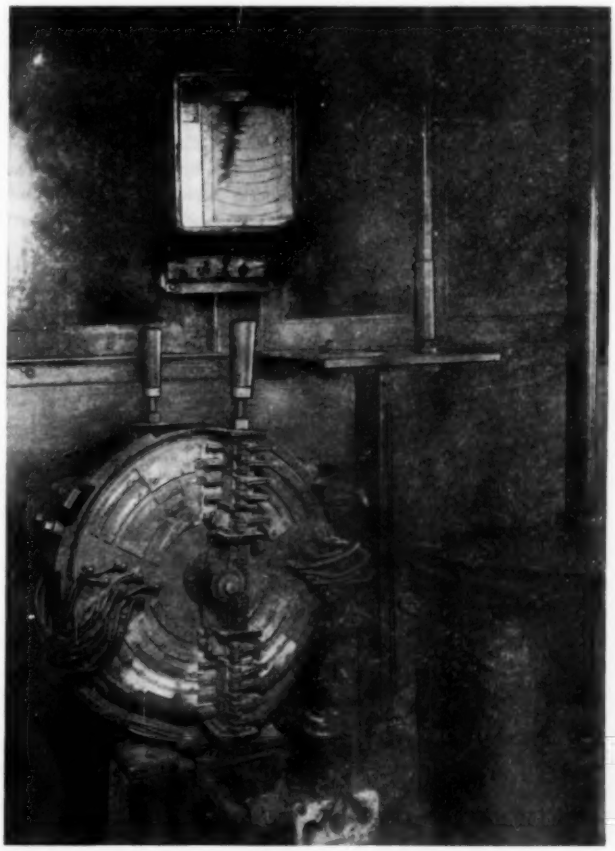

Fig. 21 Bridge-Travel Master Controllers and Anemometer Recorder

attached to ball or rail with effective clamps, or through holes in the web of rails.

2 Vertical spuds, seated in sockets in the track foundation, might be used instead of struts.

3 Manually operated rail clamps may also be used.

4 Properly shaped hardwood wedges should be placed under all wheels.

5 Watchman service should be supplied with regular clock-controlled inspection of the placing of all safety devices, with written daily reports covering conditions noted.

6 Regular inspection and tests should be made of all safety devices.

7 All parts should be kept in good mechanical and electrical condition.

Conclusion

In this discussion, the aim has not been to present new theories of protection, but rather to consider the many standard features of design and protective equipment which tend to promote

safety. If certain points have been inadvertently overlooked, it is hoped that the discussion of the paper will bring them out. Personal opinions as to relative values of various protective devices will undoubtedly vary. Operating conditions and practices may in some cases modify the conclusions set forth. While the discussion has primarily been concerned with bridge protection, many of the points taken up apply equally well to gantry cranes, unloading towers, car loaders, dumpers, etc.

For the historical references made in the first section of this paper, the author was greatly assisted by an earlier paper presented at the Minneapolis meeting of the Society in 1914 by G. H. Hutchinson, entitled "The Development of the Coal Handling Industry at the Head of the Lakes." The author also wishes gratefully to acknowledge the assistance and suggestions made by engineers of the Heyl & Patterson Company, Mead-Morrison Manufacturing Company, Wellman Engineering Corporation, General Electric Company, Electric Controller & Manufacturing Company, Cutler-Hammer Company, The Western Actuarial Bureau, and others connected with construction, controller, and dock-operating organizations.

Discussion

C. K. Steff.[2] The author has given a clear and comprehensive description of modern bridge protective devices. The paper should serve as a valuable guide in planning the protection for new equipments.

In some cases it may be possible to arrange the runway so that the most dangerous winds will strike the structure end-on. A first-class runway is worth its cost in reduced maintenance and freedom from trouble. Properly spaced creosoted ties with tie plates and supported on a heavy concrete base should be very satisfactory. The bridge builder has a definite responsibility to furnish a structure of ample stability. If wind pressures as low as 30 or 40 lb. per sq. ft. are taken, allowance should be made for windage on the leeward truss of the bridge span. New bridges should certainly have brakes acting through all wheels, utilizing the full weight of the structure, unless they are of the rack-drive type. Rail clamps have been developed to reasonable perfection only after painstaking design and field experience. This subject is not one for superficial experimenting. Rail clamps should be placed near the trucks, or preferably on a pony truck, rather than rigidly built into the center of the bridge sill where they cannot conform to irregularities in the runway beneath. Braking through all wheels is suggested as the simplest and best protective measure for new gantry cranes and unloading towers. Usually the only further protection needed is manual anchoring devices.

New equipments offer an opportunity to start right, but the problem of the majority of bridge operators is that of preserving old equipments built when modern protective devices were in stages of development and the seriousness of the wind hazard less fully realized. The problem then becomes one of estimating the value of the present protection and its shortcomings and building it up according as the value of the equipment and its importance to the plant warrants. The fundamental principles remain the same as Mr. Burton has outlined. Assuming good stability for the structure, reasonable safety during movement should be afforded by brakes acting through at least 80 per cent of the wheels and by proper electric controls. Quick anchorage is needed for important equipments, especially in windy districts, and may be obtained by a full or partial set of automatic rail clamps. Ample manual anchorage should be provided and warning given of dangerous wind velocity. Good progress is being made in building up the protection of old equipments.

Of equal importance to protective devices are the character of the operating personnel and the maintenance of the equipment. Bridges are too valuable and important to be entrusted to green operators. A bridge which is overskewed receives a very severe wrenching and is never as good again. Thorough periodic and systematic inspections by responsible plant officials are of prime importance. Bridge service is severe and parts break frequently. Employees may be slow to report trouble, especially if they or fellow employees are in part responsible for the condition. Some types of automatic rail clamps require frequent checking by the power test to insure they will be in proper adjustment to hold when needed. Outside inspection bureaus may do their best to point out unsatisfactory conditions, but at best their inspections are made some little time apart and are not a substitute for plant inspections.

W. C. Raube.[3] Although the writer is interested in all phases of material-handling bridges, he is of course most interested in the electrical equipment used to control various operations on a bridge. The author pointed out that the unstable speed characteristic of a series motor can be corrected by the use of a so-called shunted armature connection. Possibly the terms "light" and "heavy" armature shunts as used in Fig. 10 might be explained so that any one not thoroughly familiar with speed-torque characteristics of series motors would clearly understand the difference between a light armature shunt and a heavy armature shunt. Under Fig. 11 (*b*), the author shows the combination of resistances used for a shunted armature connection on a series motor. It will be noted that there is a series resistance, as shown at extreme right of Fig. 11 (B), and a resistance in parallel with the armature. For a heavy armature shunt, the resistance in parallel with the armature must have a low resistance and relatively high current-carrying capacity, while for a light armature shunt the resistance in parallel with the armature must be higher and the current capacity can be lower. Representative speed-torque characteristics for light and heavy armature shunts are shown in Fig. 10, curves (*b*) and (*c*). The high resistance in parallel with armature (light armature shunt) gives a much steeper curve than the low parallel resistance (heavy armature shunt). It will be noted, therefore, that increasing the parallel resistance increases the slope of the resulting speed-torque curve, and if this resistance is made infinitely large such as would be obtained in the path of air which we might consider connecting the armature terminals in a standard series motor, the speed-torque curve becomes very steep, and we actually obtain the more familiar series-motor characteristic curve obtained with resistance in series with the armature. The curve corresponding to this latter condition is not shown on Fig. 10, but can be visualized by sketching in a curve on Fig. 10 which at zero speed would start near the point where curve (*b*) intersects the zero speed ordinate and would then curve up so as to come very close to the upper end of curve (*a*) at 250 per cent speed. Such curve, it will be noted, is now all to the right of the vertical zero torque line.

The writer has always found it very helpful to have a good idea of the general shape of speed-torque characteristics for varying degrees of shunted armature connections and finds that an easy way to keep straight on this point is to start with the curve for a standard series motor with resistance connected in series with the armature (and which automatically has infinite resistance in parallel with the armature in the form of the air path between armature terminals), and then remembering that the speed-torque curve can be flattened out by simply reducing the resistance in parallel with the armature. The lower the parallel re-

[2] Engineer, Inspection Department, Associated Factory Mutual Fire Insurance Companies, Boston, Mass.

[3] General Electric Company, Schenectady, N. Y.

sistance, the flatter the curve becomes. Moreover, with such lower parallel resistance, the speed-torque curves will reach farther over into the braking quadrant to the left of the zero torque line.

The author made the statement at one point that the slowdown action of an armature shunt on a shunt-type motor is not quite as effective as in the case of the series motor. This statement may be misinterpreted. As the author indicates, in the case of the shunt motor, no change is made in the field strength of such motor when using a shunted armature connection. In the case of the series motor, the presence of the series resistance in the shunted armature connection limits the current taken from the line and therefore also limits the current that can pass through the series field. Maximum current will flow through the series field with the motor at standstill, but as the speed of the motor increases and the c.e.m.f. builds up, less current is taken from the line, and therefore the series field current is reduced. This process continues at higher speeds where the speed-torque curve crosses the zero torque line and passes on into the braking quadrant. This condition of field weakening of course allows the motor to run faster, and the speed-torque curve starts out at a fairly uniform slope, but breaks upward in the braking quadrant. This is particularly noticeable in the case of the light armature shunt curve, Fig. 10 (*b*). In contrast with this, we find the speed-torque curve for shunted armature connection on a shunt motor starting at zero speed and rising at a fairly uniform slope even into the braking quadrant. This, then, means that, assuming both the series and shunt motors operating at some definite speed and then applying the shunted armature connections, it will be necessary to go farther to the left in the braking quadrant before intersecting the resulting speed-torque curve for the shunt motor than for the series motor. This results in a higher dynamic braking effort in the case of the shunt motor than for the series motor. At first thought it might seem, therefore, that the shunt motor has an advantage over the series motor in this regard, and it actually has as far as getting the higher dynamic braking torque; but in order to decelerate smoothly with the shunt motor, it is necessary to put in a large number of shunted armature points, whereas with the series motor advantage can be taken of the increasing slope of the shunted armature speed-torque curves and arrange the series and parallel resistances so that the dynamic braking torque would be limited to a reasonable value, thus giving smooth deceleration with fewer steps of armature shunt connections.

D. C. Wright.[4] The author has covered safety devices for protection against wind so thoroughly that little can be added. However, the writer would like to bring up some points as regards safety of operation.

In the past it was customary to mount the master controllers for the control of the bridge-propelling motion at some point along the trolley or track runway. The operator would stop his man-trolley opposite the master controllers, walk out of his cab, and operate the masters to move the bridge to the desired point, and then would return to his cab to continue the operations of hoisting and trolleying. This mounting of the masters required no collector bars along the runway for the operation of the bridge, and made it possible to run as many wires as required from the masters to the magnetic controllers, to secure smooth acceleration from the slow creeping speed to full speed. In later years, however, the trend has been to mount the bridge master switches in the man-trolley, thus allowing the operator to move the bridge with the man-trolley in any position. This arrangement saves time and reduces the number of trolley movements considerably.

[4] Chief Engineer, Electric Controller and Manufacturing Company, Cleveland, Ohio.

There is one objection to this arrangement, in that it is too expensive to run 14 to 16 collector bars the whole length of the runway, and therefore full speed control from the master switches to the magnetic bridge controllers has to be dispensed with. Acceleration from the creeping speed to full speed has to be automatic. The rate of acceleration should not be too fast, or the wheels are likely to slip if the rails are wet or greasy. Also, too rapid acceleration will cause whipping action in the tall bridge structure and subject it to severe strains. A controller allowing only a second or less to accelerate, such as is used for mill drives, is not suitable for heavy bridge drives. Comparatively long time between closure of successive contactors is necessary to give smooth acceleration, or else a large number of acceleration contactors should be used. The bridge controllers should be selected with this point in view.

A patented control system, without extra special relays, has been devised, which allows one wire or collector bar to be used for more than one purpose, and gives proper automatic control of the two rail clamps and the two sets of bridge motors, individually or together, with but seven collector bars along the runway. Three of these are main power bars to supply power to the rail clamps and bridge motors. The other four, two for the pier end and two for the shear end, provide control for the bridge motors, giving forward and reverse motions, a slow creeping speed, and automatic smooth acceleration to full speed.

Another feature entering into safety of operation is the control of the man-trolley. Present practice is to operate these at speeds of 1200 ft. per min. or more. Weights may run up to 75 or 90 tons. Bearings are of frictionless type. Under these conditions it becomes a greater problem to stop the trolley than to start it. If it fails to start, loss of production occurs; but if it fails to stop there might be considerable damage done or loss of life might occur, besides loss of production. The more common methods used for stopping are to plug the motor or use dynamic braking. Both these methods require continuity of power supply. If the power supply fails at the critical moment, then the emergency means of stopping, by applying air brakes or magnetic brakes, has to be resorted to. These may not be in proper working order or the operator may be excited or inexperienced, and sad results may occur. The most frequent cause of power interruption is poor shoe design or rough collector bars, causing an open circuit sufficiently long to drop out the no-voltage relays during the drifting portion of travel when no power is being taken. The writer would therefore strongly recommend that all important collector bars be equipped with two collector shoes of good design, mounted, not just a few inches apart so that a particular rough spot on the bar might momentarily throw off both shoes, but several feet apart, so that at least one shoe will always be in circuit.

The rivets in bridge structure are subject to severe strain and frequently lose their heads or become loose. The writer would like an expression of opinion from bridge builders as to how frequently and thoroughly the riveting should be inspected.

The writer would like to ask the author a question as regards adjustment of the anemometer relay. Assuming that it is adjusted to lift and stop operation of the bridge at a wind of 35 m.p.h., then at what wind speed will it drop and allow resumption of bridge operation?

Frequently, with wind speeds of less than 35 m.p.h., the bridge may travel at a dangerous speed, particularly if the motor fields are inadvertently weakened or if the bridge is overmotored. It seems to me that an overspeed switch is a good safety device. This could be connected in the same circuit as the anemometer to stop the bridge and set the clamps in any case of overspeeding.

In addition to making the bridge master spring return to the off position, the connections should be such that, after the bridge

has been stopped by the anemometer or by the overspeed device, the operator should have to return the master to the off position before the bridge could be started again.

E. M. HEINSELMAN.[5] The first reading of the paper disclosed that the various items pertaining to windstorm hazards was very well covered; and even after careful study, there is but little that can be added to the discussion in so far as the installation and use of mechanical appliances are concerned. The paper is well worth the careful study of any one who is interested directly or indirectly in the construction or operation of a movable bridge.

However, it is felt that something would be lacking from this discussion if nothing were said about the importance of training the operating forces so that they will act promptly and efficiently in an emergency.

Even when a bridge is equipped with the most practical and up-to-date mechanical devices for preventing bridge losses, one still must consider the human element of first importance. Successful operation of these structures requires trained men, and the writer believes that it is a serious mistake to take the attitude that full dependence can be placed on the automatic devices for protection against windstorm damage. The operator of a bridge or a tower must be something more than a mere "lever puller," and when an emergency arises, the ground crew on a dock is just as important as the ground crew at an airport.

Without going into too much detail the writer also would like to mention a few points pertaining to bridge design, construction, and operation which he feels are of some importance. From the standpoint of windstorm protection, the driving mechanism of the bridge is important. The types of drive in common use are the lineshaft worm-gear drive, motor-driven direct worm gear, lineshaft bevel and straight gear, motor-driven direct bevel or straight gear, the cable haul with drum, and the pinion rack. In addition there is a type of drive with four individual motors, one on each corner of the bridge trucks. Each back-geared motor drives through a flexible shaft, which drives an intermediate pinion, which in turn drives a gear, which in turn through beveled gears drives a line of flexible shafting having beveled pinions mounted thereon. There are three beveled pinions on this shaft. Each pinion drives a vertical shaft through gears which in turn drive each pair of wheels independently. The writer considers this a very safe and efficient drive.

It requires a large, substantial, and expensive foundation for the pinion-rack drive bridge, but it is believed to be as safe, if not safer, in a windstorm than that mentioned. The traversing motors and brakes on this type of bridge are at the drive pinion.

There is no denying the fact that there is a great safety factor in the worm-gear drive, but it is slow moving, and for this reason it is not very popular in this swiftly moving age, and few, if any, are being built now.

An essential aim in windstorm protection is to prevent the truck wheel from beginning to turn, and for this reason the writer would place the motor-driven direct bridge ahead of either the lineshaft drive or the cable and drum haul.

On a cable-haul bridge the cable is anchored at each end of the bridge-rail foundation, and about six wraps of the bite is reaved around the drum. The cables would be anywhere from 1000 to 3000 ft. long, depending on the length of the dock. For an illustration, take a bridge standing north and south, and which moves east and west. If the bridge is moved in a westerly direction, the cable will become tight from the west end, or the end from which it is being pulled, and if there is any slack in the entire length of cable, it will be at the east side of the bridge. If a wind comes up from the east after the last move of the bridge, and there is slack in the cable from that side, then there would be some chance for the wheels to turn slightly before the moving mechanism becomes effective as a brake, and that little start may be sufficient to lose a bridge.

The writer considers the lineshaft somewhat similar to the cable haul in the aforementioned respect as the moving motor and brake on a lineshaft bridge is on top of the bridge at one end of the span. It may be a span of 300 or 400 ft. and very high, in which case there are a considerable number of couplings on the shafting between the motor and brake and the drive wheels. If the moving controller is opened slowly and the action of the lineshaft is watched, it will be noticed that the shaft will turn over from one to two turns before the truck wheel starts, and if there is any wear or lost motion in the pins and universal couplings, the lost motion in the shaft will be still more noticeable. Therefore, if a wind should start such a bridge into motion, the truck wheel is free to turn the amount of lost motion there is in the length of the lineshaft before the brake at the moving motor becomes effective.

On the motor-driven direct bridge the brake and motors are right at the truck wheels where there can be no lost motion except what little wear might come in the gearing, and that could not be more than in the other types mentioned.

Making allowance for these differences in safety, due to the various types of drive in use, it is believed that if the structure of any of these types is kept in first-class condition, and is equipped with suitable safety devices, properly maintained and applied, and is in the hands of a careful and efficient crew, it will be reasonably safe in a severe storm.

Track-sanding devices are of some value in bridge operation. However, the writer strongly recommends the electrical type and does not favor the air type even if electrically heated—due to the amount of moisture that will accumulate. The main value of sanders is for normal operations, in starting or stopping on wet or icy rails. Their value in a bad wind is doubtful, as the sand will not stay on the rails, or it may even blow away before it reaches the rail.

In addition to the bridge controls and skew-limit cut-out switches it is believed to be absolutely necessary to have a good skew indicator on each bridge. The operator, by all means, should be trained to keep his span straight by the indicator, and must not depend on any electrical or mechanical device to keep him out of trouble. In fact, he might well be told that these devices are for emergency protection only, and for this purpose they are extremely valuable.

The author has given a very good description of automatic clamps, but words about testing them would not be out of place. Apparently he suggests that all the clamps on one end of a bridge should be tested together. That is likely to be a rather severe test on the span itself. The writer prefers to test the clamps singly, and one can then cut down the power to about half. That is, if it takes two points of power to move one end of the bridge, give it one extra point. When testing two clamps together, one can never be sure that both clamps are holding. If each clamp holds, one has a good idea of what it would do in a wind. For instance, with a motor-driven direct bridge, with two moving motors on each end ranging between 35 and 45 hp. each, a three-point test on each clamp with that power would probably equal the force of a wind of 50 to 55 m.p.h. Therefore if each clamp will hold with that much power, there is reason to believe that the bridge is well secured—if it has four clamps (two on each end).

When testing clamps, if one tests the last clamp on the bridge and walks away from it, he is leaving a severe strain on that clamp. Therefore when the last clamp on the bridge is tested, all the clamps should be raised and allowed to set themselves.

[5] Manager, Tornado Inter-Insurance Exchange Bridge Operators Engineering and Inspection Bureau, Duluth, Minn.

If a bridge stands in one spot for several hours, there is some chance of the clamps loosening up from the weaving and vibration of the structure. Therefore it is a good idea for the operator to raise his clamps and reset them at quitting time, especially if the bridge has been standing in one spot for a long time.

Weather conditions affect the operation of clamps to some extent. Snow will sometimes pack into the clamps in such a way as to make them ineffective. The writer therefore recommends shoveling out the bridge tracks, keeping them free from ice, snow, coal, or other obstacles. Even under normal winter conditions, the clamps will not work as fast in cold weather as during the summer. A special test to time these clamps was made during the month of November and they were found to set in from 5 to 15 seconds. It is the writer's understanding that one bridge manufacturer thinks the clamps should not set in less than 5 seconds, and if they set in less than that they are setting too fast and will jar the structure too much.

Automatic clamps are usually installed under the truck sills, near each set of wheels, so that the clamps when set will grip the same set of rails on which the wheels rest. However, in some cases the clamps are set at the ends of the truck sill. When this is done, it may happen that the clamps will grip a different rail than the one on which the truck wheels are resting. If a heavy wind came up under such conditions, the clamps would afford little protection, as there would be no added weight on the rails they were gripping.

Placing the clamps on the outside ends of the truck sills may also interfere with operations. For instance, with two or more bridges on one dock (working on a boat), with clamps taking up 2 ft. or more of added space on each end of the truck sill, it means that the rigs would necessarily have to be 4 ft. or more further apart than without the clamps. This would often be a big handicap in working the bridges.

It is common practice to call gripping devices of this kind automatic clamps. The maintenance of these devices is very important. If neglected, they may still work automatically in an emergency, but prove entirely ineffective. It should be the aim to keep them in such condition that they will be not only automatic when needed, but also effective.

The bureau commenced inspection service during the fall of 1920 season. In looking through the engineer's reports the writer finds this notation: "When making my first trip over these properties, I found only a limited number of clamps. When the tests were made, about half of them slipped. Some of them were not in working order at all."

During the intervening years, a great many additional clamps have been installed, the management has taken a greater interest in the maintenance of this equipment, and the men in charge of the work on the docks have realized that expensive devices of this kind are useless if not properly kept up; therefore the record for the last few years shows a tremendous improvement in the effectiveness of the clamps when tested. The dock organizations now seem to take the initiative in so far as the upkeep of their equipment is concerned and do not wait to be asked to do it. In 1929 our clamp tests show that only 5.2 per cent slipped at the time of the inspection, and many of these were merely out of adjustment and were put in first class condition at the time. To make some of the others hold it was necessary to install new shoes, inserts, or liners.

The increasing efficiency in the gripping power of automatic clamps is due to several reasons. First of all, the various bridge-construction companies are keenly interested in this feature, and all of them have made improvements in the kind of clamps they furnish. Second, as already stated, the management and employees now realize that it is very important to maintain the clamps in first-class shape.

In the early days of our work it sometimes happened that we would find all the clamps on a bridge ineffective at the time of inspection. This has not occurred for several years. Of course, it is possible for the clamps on one end to slide because of a beaded rail, uneven foundation, etc., but the other end should hold.

The author has mentioned the importance of keeping the rails and foundations in good condition.

There are still some steam rigs in service, and there are still a few places where it is necessary to build steam rigs, due to the fact that electric power is not available or there is a limit to the power that can be furnished.

Many of the steam bridges are equipped with automatic clamps, but on such installations a power test of the automatic clamps is almost impossible, and we do not believe should be attempted.

On these rigs there is no correct way of measuring the amount of power, and the operator is liable to give a clamp much more than it should have. Occasionally a test can be made by pulling a locomotive or similar machine against the clamps. When pulling against the bridge in this way, it may be possible to measure the pulling strain, but in no case do we consider it advisable to apply the steam against the clamps.

On steam installations about all an inspector can do is to examine the clamps carefully when he makes his rounds, and check up the imprints on the rails from the gripping surfaces, and inspect all wearing parts of the clamping mechanism.

There is still another type of bridge which has not been mentioned; that is the pivot bridge. This is pivoted at one end and circles the yard. The value of clamping down such a bridge in case of an approaching storm is doubtful. Some take the position that it should not be tied down, for if a wind came up, the pivot bridge would swing in a wide circle to the point where it would settle down with an end wind behind it.

The writer would also like to say a little more about the wooden wedges mentioned by the author. His first choice for material is basswood. However, basswood planking is rather scarce and cannot always be readily obtained. The second choice is maple, and this can be obtained in any part of the country.

In shaping these wedges, care should be taken so that the contour will allow the truck wheel to ride the point first before it engages the main protion of the block; otherwise the wheel will have a tendency to push the block ahead of the wheel.

Some operators think it is a good idea to paint the wedges. If they are painted a distinctive color they are easy to find when there is an emergency and they must be put in quickly. They are also easy to find when it comes time to take them out, and there is less chance of leaving one block in under the wheel when starting up the bridge.

As to the effectiveness of wedges, with sound wedges of proper shape it has been found impossible to start up a 50 per cent drive bridge with four wedges under the wheels, or with eight under a 100 per cent drive bridge, but of course one can run over them if the bridge is under way.

There is some difference of opinion as to the relative value of wood and steel wedges. The writer prefers the wooden wedge. It is easier to insert, it costs less, and there is less chance of damage to the flange of a wheel when bucking against a wooden wedge.

There is but little that can be added to the outline given by the author in dealing with rails and foundations. However, the writer has in mind several dock properties that are served with railroad tracks that cut across the bridge rails. This is a big handicap in the maintenance and use of both manual and automatic clamps. These crossovers also tend to break the flanges of the bridge wheels. In planning a dock, this condition should be avoided if at all possible.

During the past season it was found on a few properties that when renewing rails they put them in "staggered fashion" on the two-rail runways. The disadvantage is that there are twice as many places for the clamps to strike against the fishplates or the bolts. However, when clamps are found to be striking, they can usually be elevated with little difficulty, and still engage the rail in proper fashion. The advantage of staggering the rails (and it is a big one in the writer's opinion) is that it minimizes the pounding on the foundation at the rail joints. Where there is a double rail joint and the bridge hits the ends of the rails, there is a big weight at the ends of the rails, and eventually it pounds a hole in the concrete. If the rails are staggered, there is also some advantage when applying the clamps (either automatic or manual) as they are grabbing different sets of rails.

When there is a wind of 35 m.p.h. or more, it is dangerous to move the bridge, even if it is an end wind, as the wind can veer without an instant's warning. If the bridge is in motion when the wind turns and the clamps set automatically, that in itself may create a dangerous condition; besides, if the bridge is moving at a rapid rate when the clamps grab, it is doubtful if they would halt it.

In addition to the foregoing comments, there are a few odds and ends that may be mentioned to good advantage. For instance, it may not be out of place to say something about the type of bridge which is constructed with the skewage at the bottom, rather than at the top. In such structures it does not give a very wide spread at the bottom. Therefore, it is believed that such a bridge is more hazardous in a storm. The writer knows of two cases where such bridges have gone down, because the bottom skewed right off the skew rollers. In one case this happened when the bridge came into contact with another bridge.

One superintendent recently suggested that it might be a good thing to provide a trough of sand over the rails near the bumpers.

There is no hard and fast rule for estimating the operating life of a bridge, but there seems to be an opinion that with a good structure, operated under normal conditions, the owner should get at least 20 years of satisfactory service from it.

It is of course understood that the parts that are subject to wear should be replaced from time to time as needed. However, the writer knows of one bridge in ore and coal service that is approaching 30 years of use. This bridge is in very good condition today. The parts exposed to wear have been renewed when necessary, and rust-eaten members have been replaced. On the other hand, the writer knows of a bridge in ore service exclusively where the structure and driving mechanism were so bad after 18 years of service that the bridge was condemned and taken down.

In the earlier days of bridge building, it is believed, the percentage of overstress allowed was considerably less than today, and increasing the percentage should tend toward longer life for the newer structures.

Mention of the life of a bridge may seem like straying away from the subject under discussion, but the main reason for bringing it up is because the bureau's records indicate that two of the losses occurring during the last ten years were due to weakening of the structure by corrosion, battering of sills, and members by the bucket, etc., and this factor is of increasing importance as the structures grow older.

A study of the wrecks which have occurred during the past ten years shows that there were comparatively few losses due to cyclones or tornados. The majority of the bridges were lost in strong gales. Some were lost because the bridges were moving in dangerous wind velocities, when they should have been tied down. Others were lost because the safety equipment had been neglected. For instance, in one case the solenoid brakes were entirely ineffective. In another case the bridge was lost in a 48-mile wind, because the clamps were not kept in adjustment.

Others were lost because of certain peculiarities in construction to conform to the type of service required; for instance, light bridges on top of lime and salt storage warehouses.

Probably some bridges were lost because there was no effort on the part of the operating force to tie up in the face of an approaching storm, or because those efforts were delayed too long.

Due to the fact that it is very expensive to cut out a furnace for want of raw material, there has at times been a tendency to take a chance on the safety of a bridge in ore service, when wind conditions were dangerous. When engineers are planning an ore dock, they should give full consideration to the value of furnishing sufficient ore bins so that the operator could have a supply on hand, available for the furnace, during a storm, and the bridge could then be tied up without interfering with the blast-furnace operations.

It may not be out of place to end this discussion with a few words on operating practice. Even after one has installed all possible safety devices, he is still dependent upon the human element for operation of the bridge, and to some extent for the application of the safety devices.

It is the bureau's practice to invite all superintendents of the various properties to a two-day meeting, held each spring, at which time all problems in connection with the operation of bridges and towers are discussed in detail. At these meetings our operating rules are revised. We also issue windstorm bulletins annually, and these bulletins and the rules are posted in each dock office and in each bridge cab, where they are in full view of the operator.

In addition to the visits made by the inspecting engineers, a committee of superintendents goes over each property once a year.

At various times during the year unusual conditions are taken up in circular letters and bulletins are sent to the interested parties, and four times each year we issue a small paper entitled "Loss Prevention," which deals with subjects pertaining to the operation of bridges and towers.

These things are done to acquaint all the interested people in all conditions which may affect the operation of their properties and to enable them to take steps to prevent damage to their equipment.

Just what an operator can do in an emergency depends on the man and also on the conditions under which he is working. If he is moving down the track with a wind and sees that the wind is getting the best of the structure, he may signal for help. If there are men at both ends of the bridge, they can put the blocks or wedges into place. If the clamps fail him, he has an opportunity to reverse the power.

Sometimes when unloading boats, if a high wind comes up, and it is necessary to move, it may be far safer to move the boat rather than the bridge. However, if an operator is working a certain section of the dock and this gets filled up, then he will have to move the rig or shut down.

From the standpoint of preventing windstorm losses, the bridge operator is an important man. Employers realize this and take particular pains in securing good men for this position. They also make certain that these men are properly trained before the bridge is left in their hands. Some employers make it a practice to hire oilers with the idea that they will eventually qualify as operators. When an intelligent man is employed as an oiler, he has an excellent opportunity to learn the duties of an operator within a comparatively short time.

When the first bridge is installed on a new property, the training of the operator is often left to a special man employed by the bridge builder. When this is done, it is advisable to get as many men as possible familiar with the operator's job, as, if the regular

operafor quits, is discharged, or is disabled, the employer might have some difficulty in securing a competent man on short notice.

We were recently asked the question as to the proper place to tie up a bridge. If you are going to tie up a bridge for a week or ten days, put it up against the bumper at the far end from the direction of the prevailing winds. We know of cases where the owner has constructed the dock foundation with a slight grade against the prevailing wind, making the bridge move harder in that direction than it would in the other.

In an emergency, the operator will of course tie up the bridge wherever he may be. If the boom is up, he will leave it up, as this is probably the safest place for it. For instance there may be a boat in the slip, and if the bridge goes down, with the boom lowered, it is going to strike the boat.

In spite of the many devices that are designed to guard against or prevent windstorm losses to these expensive structures, the writer wishes to again emphasize the importance of the human equation. There is a safety axiom to the effect that the careful workman is the best safety device known. That is almost equally true in the prevention of bridge losses.

With a structure in the hands of a careful operator who has been thoroughly coached as to his responsibilities and with a ground crew that is ready to assist in anchoring the bridge when there is a possibility of a destructive wind, one can be sure that the protective devices will be used to good advantage.

No matter how good the mechanical safeguards may be, if they are not kept up at all times and used in an emergency, they are of small value. One cannot stress too strongly the importance of bringing home to the men their individual responsibility for the safety of the bridges under their care.

G. H. Hutchinson.[6] The author has rendered a distinct service, not only in clearly setting forth the importance of adequately safeguarding movable material-handling bridges and similar structures, but also in bringing together such a full statement of present-day practice in this important field.

It is evident that the better we understand wind and its action in general, and the fuller knowledge we have in regard to local wind conditions to be dealt with in individual installation, the more effectively provision can be made to avoid wind damage. In safeguarding structures of the movable bridge type against wind each installation requires that consideration be given to the magnitude and general proportions of the structure, to the features of exposure and accessibility, to the requirements and limitations of operation, to the direction, intensity, and general character of the winds prevalent or likely to occur in the district or at the site, to the probable effect on the structure of the wind found likely to occur and finally to the provisions for making the structure safe under conditions found to obtain.

Fluctuating Winds

There appears to be no fixed relation between velocities of momentary peaks or gusts and average wind velocities, even for comparatively short periods, the ratio fluctuating widely with the character of the wind, which in turn is influenced by geographical location, topography, seasonal conditions, and by the the direction of the wind, especially when near large bodies of water. A casual examination of the accompanying anemometer charts, Figs. 22 to 29, moving at the moderate speed 3 in. per hour, would appear to indicate that in high winds at the head of the Great Lakes where the charts were made in exposed location at elevation of about 140 ft. above lake level, momentary peak velocities ranging from 50 to 100 per cent above the average velocity for 5-min. periods are not unusual. While the isolated maximum momentary peak alone may not be the critical wind, this, together with the accompanying repeated lower peaks or gusts of longer duration, may at times be the determining factor in causing damage. This makes it essential in selecting the governing velocities in safeguarding movable bridges that the peak velocities be given due weight in relation to the average velocities reported by the U. S. Weather Bureau as "maximum" and "extreme" velocities for 5-min. period and for 1 mile, respectively.

In commenting on results of the Mt. Washington experiments which he made for the U. S. Weather Bureau, (1)[7] Professor Marvin states in regard to peak velocities and the possible cumulative effect of recurring peaks, "It is important to note that momentary pressures as much as 35 per cent above the mean pressure (for a 5-min. period) may continually occur and recur. If their rate of occurrence be at all synchronous with a natural time of vibration of the structure of any part thereof, remarkable effects may follow."

Value of Experiments

The experimental work of Langley (4), of the U. S. Weather Bureau (1), and of Eiffel (5), together with that of numerous earlier experimenters, largely with winds of low or moderate velocity, has been of great value in establishing formulas for "corrected" wind velocity and for velocity-pressure ratio and in determining tentative values of pressure coefficients obtaining under various conditions as to size, inclination, shape and aspect, and interrelation of surfaces subject to wind pressure

The aforementioned experiments were confined largely to low-velocity winds acting on thin, flat plates, and were thus limited in respect to two important features. For ultimate data applicable to skeleton steel construction, experiments with high-velocity winds acting on structural members of various shapes are needed. The modern large high-velocity wind tunnels which have been devoted thus far principally to the development of aeronautics would appear to be adaptable to experiments on composite structural members or even on models of entire structures of skeleton type.

Several years ago the U. S. Bureau of Standards conducted a series of tests on a model of a tall, square building with wind at "true" velocity of 76 m.p.h. However, owing to the shape of the model, the results are not applicable to skeleton construction. The report (9) on these experiments states, "Loads produced depend on the form of structure. . . . We know now that measurements on a flat plate do not give results applicable to the side of a building. There is no definite pressure corresponding to a given wind speed applicable to all types of objects; many experiments are now available which enable a general survey of the effect of form variation, but many more measurements are needed on models resembling more closely actual structures."

However, the report further states, "We believe that we must know what takes place in a uniform wind under controlled conditions before we can hope to find out what happens in a gusty wind. . . . When this preliminary information has been obtained, work may be begun on a structure of simple type on exposed location in natural wind."

The investigation (10) of wind pressure on several spans of a railway bridge, for which preparation was being made in 1929 by the National Physical Laboratory in continuation of the investigation at Eddington initiated by Dr., now Sir Thomas Stanton, in 1902, should throw considerable light on the characteristics of wind pressure on full-sized skeleton steel structures in exposed location. The scope of these experiments is indicated by the fact that it is intended to record the maximum and the mean pressure occurring simultaneously on the two halves of a half mile section of a rail-

[6] Engineer, Davison Coke and Iron Company, Pittsburgh, Pa. Mem. A.S.M.E.

[7] Numbers in parentheses refer to Bibliography at end of the discussion.

way bridge composed of 22 spans ranging from 134 feet to 327 feet in length.

Experiments of the nature outlined by the Bureau of Standards are greatly needed, but until data specifically applicable to each of various types of construction are made available, the results obtained by the earlier experimenters, which in considerable measure still form the basis of our present knowledge of wind action, will continue to be of great value in engineering calculations. With this in mind, the writer presents the following data taken from matter gathered from various sources for personal use, believing that this information has not been previously presented in convenient form for reference.

Inclined Wind

Duchemin's (2, 3) formula,[8]

$$P_N = (P_H^2 + P_V^2)^{1/2} = P \frac{2 \sin \theta}{1 + \sin^2 \theta}$$

for normal component of pressure from inclined wind acting on plane surfaces gives normal pressures much greater than would be derived from resolution of forces. By this formula, the normal pressure of a wind, the axis of which is inclined at an angle of

25 deg. to the surface is about 72%
65 deg. to the surface is about 99.5%
45 deg. to the surface is about 94%

of the pressure on a plane placed at right-angles to the direction of the wind.

The results of Langley's (4) experiments on wind at velocities ranging from 11 to 67 m.p.h. correspond closely with those deduced from Duchemin's formula.

The foregoing indicates the need of giving careful consideration to the effect of the large resultant pressure due to horizontal winds making critical angles with the axes of structures of the type in question. In the absence of experiments with inclined winds on the types of members involved, it would appear advisable to make provision to withstand the resultant of normal pressures from the large axial and lateral components on the exposed transverse and longitudinal surfaces, respectively. According to the formula mentioned, it will be noted that wind inclined at an angle of 45 deg. to the bridge axis would simultaneously produce axial and lateral pressures equal to about 94 per cent of the corresponding pressures which would result from axial and lateral winds acting separately at different times. However, it should be borne in mind that the area of transverse and longitudinal surfaces subject to normal components of pressures from a diagonal wind will be somewhat different from the area of corresponding surfaces exposed to the aforementioned axial and lateral winds acting separately, the difference depending upon the type of construction and the arrangement and sections of members.

It may be of general interest to note that Eiffel (5) in commenting on his experiments with low-velocity winds says: "The most unexpected result was the sudden increase in the resistance of a square plate inclined 37 deg. to the wind to a value 50 per cent greater than the resistance of the same plate normal to the wind." Eiffel with other experimenters recognized that a considerable percentage of the high normal pressure from inclined wind is due to vacuum on the rear of the plate. In view of the limited possible total vacuum at any velocity, the ratio of vacuum to positive pressure in high destructive winds will necessarily be much smaller than with low winds, indicating the probability that the relatively high percentage of normal pressure from inclined wind noted by Eiffel would not be maintained in high winds.

Langley's (4) experiments do not show any sudden rise in normal pressure from wind inclined at 37 deg. or that there is a critical point in the pressure curve for winds inclined at from 0 deg. to 45 deg., the range for which experiments were made.

Uplift

The uplifting tendency frequently attributed to tornadic winds and the vertical component of winds deflected upward by the inclined sides of high coal and ore piles indicate the desirability of recognizing the effect of this possible uplift of unknown but apparently considerable amount in calculating the stability of bridges against overturning and skidding and in reduced tractive effort available in traveling against the wind. Entirely aside from the element of reduced available tractive effort due to uplift, it is not the custom under conservative management to attempt to traverse bridges in either direction in high winds unless in emergency it be for the purpose of squaring them up with their tracks when blown into skewed position by the wind.

Pressure Formula and Coefficients

The U. S. Weather Bureau (1) formula, as derived by Marvin from the 1890 Mt. Washington experiment which he conducted for the bureau, expressing the relation between wind velocity and pressure, is:

$$P = 0.0040 \frac{B}{30} V_c^2$$

in which

P = pressure in pounds on a plane surface exposed normally to the direction of the wind
0.0040 = pressure coefficient, frequently expressed by K
B = barometric reading in inches of mercury
($V_c = V$, used by Marvin) = the "corrected," "true" wind velocity in miles per hour.

At elevations near sea level, the barometric factor becomes approximately unity and can be disregarded. The Weather Bureau still retains the value 0.0040 for the pressure coefficient, which may be expressed by K, while recognizing a lower value deduced from later experiments as probably more correct.

In 1915 one of the division chiefs of the Weather Bureau stated: "However, care should be used in applying wind-pressure formulas, since it is obvious that the wind-velocity factor is quite an uncertain one. Even where there is a free wind exposure for a given structure, the wind velocity would increase with altitude, and be modified by the peculiarities of shape of the structure itself. A large margin of safety in the application of the formula

---

[8] Duchemin's formulas for ordinary air pressures per square foot on thin stationary flat plates inclined to the wind are, with slight changes in wording to adapt them to structural design, as follows:

$$P_H = P \frac{2 \sin^2 \theta}{1 + \sin^2 \theta}; \qquad P_V = P \frac{2 \sin \theta \cos \theta}{1 + \sin^2 \theta};$$

$$P_N = (P_H^2 + P_V^2)^{1/2} = P \frac{2 \sin \theta}{1 + \sin^2 \theta}$$

in which

P_H = pressure parallel to the wind
P_V = pressure perpendicular to the wind
P_N = pressure normal to the surface
P = pressure on the same plane when normal to the wind, for which limiting condition $N = P \times 1 = P$
θ = angle between the wind and the surface.

The derivation of the last member of the expression for P_N is evident from the following:

$$P_N = (P_H^2 + P_V^2)^{1/2} = \left[\left(P \frac{2 \sin^2 \theta}{1 + \sin^2 \theta}\right)^2 + \left(P \frac{2 \sin \theta \cos \theta}{1 + \sin^2 \theta}\right)^2\right]^{1/2}$$

$$= \frac{P}{1 + \sin^2 \theta}\left[4 \sin^2 \theta (\sin^2 \theta + \cos^2 \theta)\right]^{1/2} = P \frac{2 \sin \theta}{1 + \sin^2 \theta}$$

as given above.

Pressures are per square foot of surface pressed.

is therefore necessary. In this connection, recent experiments indicate that the constant in the formula 0.0040 is somewhat too high, and that 0.0032 would probably be more correct." This statement is pertinent, and in consideration of its source, should carry much weight. While the Weather Bureau obviously is wise in not adopting a new coefficient precipitately or until one sufficiently reliable to merit general recognition has been deduced and confirmed by extended and repeated experiments, it would seem logical for engineers in their calculations to make the necessary allowance for uncertainties as to velocity incident to high

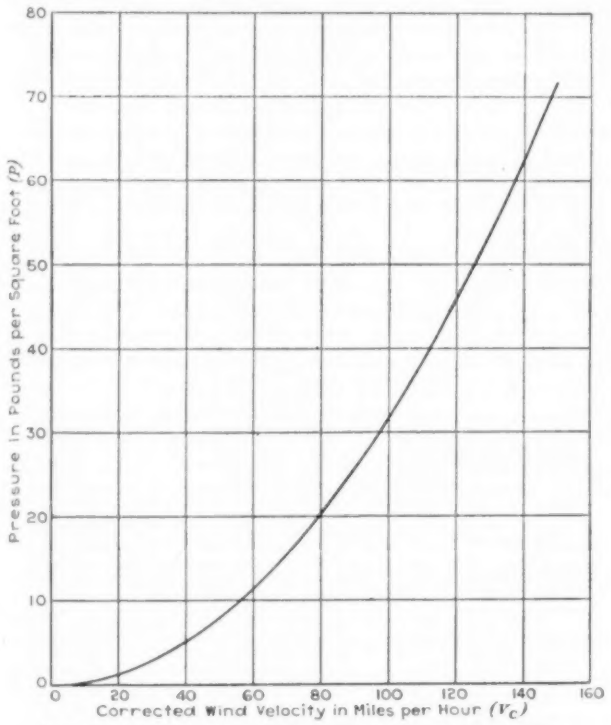

FIG. 22 WIND VELOCITY-PRESSURE CURVE FROM FORMULA

$$P = K\,(B/30)\,V_c^2$$

(For elevations at or near sea level, for which altitude $(B/30) = 1$ approximately.)

in which K = pressure coefficient, assumed at value of 0.0032 for this curve (U. S. Weather Bureau uses 0.0040 for value of K)
B = barometer reading in inches of mercury
V_c = corrected wind velocity in miles per hour
P = pressure in pounds per square foot

(From Weather Bureau formula with modified coeffcient K.)

elevation, wind fluctuations, and other causes in the velocity factor V_c, leaving them free to select for the pressure coefficient k, the best authenticated value available at the time.

Langley (4) from his Allegheny experiments, 1888 to 1890, deduced an average value for k of 0.00357.

Eiffel (5) from his experiments, conducted from 1902 to 1913, derived a value of k applicable to English units for square plane surfaces normal to the wind ranging from 0.00266 for plates 10 cm. square to 0.00323 for plates 1 meter square. Eiffel remarks, "This latter figure is probably the upper limit."

Stanton (6) found for k the value of 0.0027 for plane surfaces 2 in. sq. and 0.0032 for plane surfaces 5 ft. sq. and also for plane surfaces 10 ft. sq.

Values for pressure coefficient k ranging from well above 0.0040 to considerably below 0.0032 have been derived by various other experimenters with wind at moderate velocities. The range is so wide as to indicate the need of further experiments to determine a pressure coefficient or coefficients which can be safely and economically applied to moderate and also to high destructive velocities. A velocity-pressure curve and table are given in Fig. 22.

Also there is need of fuller and more definite knowledge in regard to velocity and pressure fluctuatons in high-velocity, highly fluctuating winds from which can be determined at least an approximate relation of the practical effect of the high peaks to the effect which the pressure formula would indicate for the average velocity for a 5-min. period and for 1 mile reported by the Weather Bureau as "maximum" velocity and "extreme" velocity, respectively.

Fortunately, fairly full information in regard to velocity fluctuations is obtainable, and the inclusion by the author in his paper of a somewhat extended series of typical high-speed charts similar to that shown in his Fig. 3, traveling fast enough to clearly indicate the velocity fluctuations and to permit determination of average velocities for selected periods, and the general range of ratios of peak to average velocities, would be of much value. From these and similar high-speed velocity charts, the corresponding theoretical pressure fluctuations could be determined by the pressure formula.

The direct determination of pressure fluctuations for high-

45	37.1	90	69.2	140	103.1	...	.....

velocity, widely fluctuating, natural outdoor winds in exposed location would not be so readily accomplished, but if a simple practical means were devised of directly graphically registering not only velocity but also corresponding pressure fluctuations for normal and inclined winds under the foregoing conditions, the

data thus made available would be of still greater value and make possible the derivation of pressure coefficients applicable to normal and inclined destructive winds.

(Preceded and followed by low wind.)

correction, or to "corrected" or "true" velocity, while under each of these heads, reference may be intended to a momentary velocity or to average velocity over one of several possible periods.

Wind velocities recorded by the U. S. Weather Bureau are average velocities in miles per hour. Velocities or travel for four selected periods are entered daily in the Weather Bureau records, namely:

(*a*) "Maximum" velocity, which is the highest average "recorded" velocity for any consecutive 5-min. period in a 24-hour day.

(*b*) "Extreme" velocity, which is the highest average "recorded" velocity for 1 mile which occurs in a 24-hour day.

(*c*) The average velocity or travel for each of the 24 hours of the day.

(*d*) The total wind travel during the 24-hour day.

The "maximum" "recorded" velocity is the one ordinarily given out by the Weather Bureau, and is therefore the velocity commonly known or referred to. The "extreme" "recorded" velocity and the other velocity data aforementioned can, however, be ascertained from the Weather Bureau upon request. the "maximum" velocity can be determined from observation of the chart while still in the instrument, while the "extreme" velocity can be obtained only by scaling after the chart has been removed at the close of the day.

Inasmuch as the ratio between the linear velocity of the cup centers of the Weather Bureau type of the Robinson anemometer and that of the wind is not constant, but increases at an accelerated rate as the velocities increase, the "recorded" velocities as registered by the anemometer are not "true" velocities, for the determination of which a logarithmic formula derived by the Weather Bureau from experiments is required.

The commonly used wind pressure formula is based on "true" and not "recorded" or "indicated" velocity, although it is the "recorded" velocity to which reference is commonly made. A corrected velocity curve and table are shown in Fig. 23.

The formula for "corrected" velocity, with slight change in symbols, is:

$$\log V_c = 0.509 + 0.9012 \log \frac{V_i}{3}$$

in which

V_c = "corrected" or "true" velocity of wind in miles per hour

V_i = "recorded" or "indicated" velocity of wind in miles per hour

$\left(\frac{V_i}{3} = v \text{ of the original formula}\right)$ = linear velocity of cup centers of anemometer in miles per hour

$= \frac{1}{3}$ "recorded" or "indicated" wind velocity in miles per hour.

The writer wishes to acknowledge his indebtedness for data used to the several works listed under Bibliography, to which the index numbers in the text refer.

Anemometer charts are shown herewith (Figs. 24 to 31, inclusive), that were selected to show high peaks and characteristics of fluctuating winds of several types at Superior, Wis., at the head of the Great Lakes.

These charts were made by a Burton recording and indicating anemometer mounted on the mast of the North Western Fuel Company's No. 5, 551-ft. clear-span coal-handling bridge. Each chart shows a curve for about a 3-hour period. The duration of similar wind condition of reduced intensity is indicated by notation for the individual charts. The chart travel is 3 in. per hour. "Recorded" velocities are shown and specified.

Author's Closure

The author is pleased to note the favorable comments of various discussors of the paper presented. The aim in its preparation was to cover the whole field as well as possible without making the presentation unduly long. Many of the features of construction, control, or protective equipment might have been greatly elaborated upon, and many individual or special cases discussed, but only a general discussion was considered possible. Several of the discussors have made comments which undoubtedly add to the completeness or clarity of certain points, and the author appreciates their interest. In some cases, questions have been raised to which the writer wishes to reply.

Mr. D. C. Wright has requested information as to the adjustment of the anemometer relay used by the author. This relay can be adjusted to trip at a given velocity and to reset at a wide range of lower velocities. Assuming a tripping point of 40 m.p.h., the contacts may reclose at 38 miles or 35 miles, or 30 miles, or any point intermediate or below these values. In general, a three- or four-mile differential is desirable, since better protection is thus obtained, and any tendency to rapid opening and closing of control circuits or "fluttering" when the wind velocity fluctuates a little above and below the tripping value is eliminated. This relay has another operating characteristic which also tends to promote increased safety in operation. Magnetic hysteresis of the relay frame causes the tripping and resetting point to become temporarily lowered after exposure to high wind velocities. In other words, with a normal tripping adjustment of 40 miles and a reset point of 37 miles, a wind velocity peak of 60 to 70 miles may reduce the tripping points, as the wind decreases, to 38 and 35 miles, respectively. Higher peaks may further reduce the settings. This temporary effect is partially erased as the wind drops down to 10 or 15 miles, and completely disappears when a calm occurs. To put it in other words, the relay "remembers" the high peak velocities, and enforces greater operating caution until the storm is over.

Mr. Heinselman emphasizes the importance of proper training and experience of bridge operators, and the author heartily concurs in these remarks. Cautious and well-trained operators constitute in themselves a great safety asset. The instruction and education of dock superintendents and their forces in the effective use and maintenance of all safety appliances through

inspection bureau bulletins and reports also contributes a great deal toward the prevention of losses.

The author is convinced that the methods of testing the effectiveness of rail clamps and similar devices are in many cases too indefinite and uncertain. There are so many types of motor and control equipment, and so many types and percentages of traction, cable or pinion drives, that a general rule to apply "two or three points of power" or "until drive wheels slip," is quite useless. Undoubtedly each clamp should be tested separately, with an ammeter connected in the motor circuit so that the pressure against the clamp under test may definitely be determined. A certain current value should be set for each individual bridge by the inspector or bridge builder, under which the clamps must hold. The author has found that good clamps in good condition will hold singly up to 150 to 200 per cent or more of full load current applied to both series-wound motors on each leg of a four-motor bridge. The torque developed by shunt-wound motors at 150 to 200 per cent load current would naturally be considerably less than in case of series motors, and in case of induction motors 150 to 200 per cent load would represent a still lower torque or propelling force. The bridge builder or designer would seem to be the logical authority to specify the current value which will constitute an adequate test. A very little oil or grease on the rail may cause the wheels to slip at 100 per cent load or less, while oil or grease on the clamping surfaces may cut the holding power of the clamp in half. A monthly test of each clamp backed up by a graphic recording meter chart showing the actual test current might be suggested as a most effective system. Similar metered load tests might also be made against the solenoid brakes applied to the travel motors.

In the testing of rail clamps, on steam-propelled rigs, the author wonders if suitable and effective tests could not be made with temporarily reduced boiler pressure applied direct to the propelling engine. This would seem to eliminate the possible danger of full-pressure tests.

To insure 100 per cent effective operation of rail clamps, it is important that worn or defective parts be replaced promptly with genuine replacement parts supplied by the manufacturer, or with parts which are known in every way to duplicate the physical and metallurgical properties of the original parts. For instance, certain highly stressed parts of a cam-operated rail clamp are made of heat-treated alloy steels to safely withstand the enormous gripping pressures exerted under power tests or under wind pressure. The ill-considered substitution of steel parts of low elastic limit and low tensile or compressive strength may almost completely ruin the effectiveness of the clamp.

The effectiveness of wood or steel wedges of proper form when applied to *idler* wheels can hardly be questioned. However, there is some doubt as to their value on 100 per cent wheel-driven bridges. If the solenoid brakes are effective, the wheels should slide on the runway rails without turning. The author is familiar with several cases where at least one end of a bridge was moved by a storm for some distance along the runway with the wheels locked and sliding. The flat spot on every wheel furnished incontestable evidence that the wheels did not rotate. If the wheels do not turn, they will simply push the wedges along ahead of them without any appreciable retarding effect.

The collection of wind-pressure and wind-velocity data, formulas, and tables arranged by Mr. Hutchinson brings together a great deal of scattered information, frequently difficult of access, and this section ought to be of particular interest to engineers whose work may include wind-pressure problems. The remarks and explanation covering the proper understanding and interpretation of the various terms used in referring to wind velocities ("recorded," "observed," "indicated," "corrected," "maximum," "extreme," etc.) are also pertinent and valuable.

Mr. Hutchinson does not mention the recent change (1928) of the Weather Bureau from the Robinson four-cup anemometer to the Ferguson three-cup model as the standard instrument of the bureau. The new three-cup instrument has a much smaller error than the older four-cup instrument, and at all ordinary velocities may be considered substantially correct.

The following condensed correction tables show the comparative correctness of the indicated velocity values of the two instruments:

Old Four-Cup Anemometer

Indicated velocity, miles.....	5	10	20	30	40	60	80	100	120	140
Corrected velocity, miles.....	5	9	17	25	32	47	62	76	91	106

New Three-Cup Anemometer

Indicated velocity, miles...	5	10	20	30	40	60	80	100	120	140
Corrected velocity, miles...	5	10	20	29	39	58	77	95	114	133

The author may point out that the velocity record charts, Figs. 3 and 4 of the presentation, as well as the charts, Figs. 24, 26, 27, 28, 29, 30, and 31, furnished by Mr. Hutchinson, are all made on the basis of "indicated" velocities of the Robinson Scale, and are subject to correction for true velocities according to the Robinson Correction Table. Current anemometers of the Burton type are now calibrated according to the new standard of the Weather Bureau.

Manufacture of Large Weldless Forged-Steel Pressure Vessels

By JOHN L. COX,[1] PHILADELPHIA, PA.

This paper describes in detail the various steps taken in the manufacture of large weldless forged-steel cylinders for high-pressure boiler drums and for various uses in the oil-refining and chemical industries. It covers the melting, casting, and heating of the ingot; cutting-off, piercing, and expanding the billet; forging, treating, and machining the cylinder; and illustrates a number of ways in which the ends of the cylinder can be closed.

DURING the last few years a great change has taken place in several important industries in the United States. Formerly almost entirely dependent on Europe for our dyes or the intermediates from which they were made, the years since the Great War have witnessed an astounding growth in our manufacture of chemicals, which has resulted in our practical emancipation from this dependence.

Once our only source of nitrogen in quantity was Chilean saltpeter, sodium nitrate, of which the War Department carried an enormous stock to provide for contingencies. The substitution of manufactured for natural ice and the more extensive use of fertilizers as our virgin lands lost their fertility have called for ammonia and nitrates in great quantities, a demand now largely met by the fixation of atmospheric nitrogen.

Gasoline, once a troublesome by-product in the production of kerosene, through the perfecting of the internal-combustion motor has become the most valuable petroleum product. Every means that could increase its yield has been eagerly sought, and it has been discovered that destructive distillation under pressure would in some cases increase the yield as much as thirteenfold.

The necessity for the more economical generation of power has led to a great increase in boiler pressures and dimensions. Today no one comments on a pressure of 1400 lb., and much higher pressures are in actual use.

These advances have been made possible largely through the development and general introduction of steel vessels sufficiently capacious for large-scale operation and strong enough to withstand high pressures at temperatures generally elevated. When the requirements are not too severe, riveted or welded vessels may answer satisfactorily, but the most exacting service requires the use of weldless steel vessels, forged entire in one piece. It is with the manufacture of such vessels that this paper deals.

The making of a good cylinder begins in the open-hearth furnace. The steel may be either acid or basic open hearth, the acid process being preferred for steels of high quality as it affords better opportunity thoroughly to settle up the metal. If very low phosphorus and sulphur are demanded, it may be necessary to use the basic process because of the difficulty in securing suitable raw materials for the acid furnace, or the impurities may be reduced by the basic process and the metal finished on the acid hearth.

In both cases the steel is carefully melted, brought to good condition in the furnace, where practically all the finals are added, and a very moderate addition is made of deoxidizers to basic metal, none to acid. Generally the service requires only a carbon steel, but sometimes a stronger alloy steel must be used, and at times special conditions may require the use of special compositions. Thus for the synthesis of ammonia it has been found that a steel with carbon below 0.30 per cent and containing about 2 per cent or more of chromium and 0.18 per cent of vanadium is especially suited, being very resistant to intergranular penetration by hydrogen.

Since it is important that the steel be as free as possible from sonims, good practice dictates that it be melted hot, and instead of being poured at once into the ingot mold from the ladle into which the furnace is tapped, that it be held in the ladle as long as is considered prudent for the size and temperature of the heat, so as to afford ample time for the particles of slag to coalesce and, by virtue of their less specific gravity, to rise to the surface of the steel. For a 70-ton heat of 0.25 per cent carbon steel this time of holding may be as much as half an hour.

For very large ingots it is necessary to combine the heats of several furnaces. Arrangements must be made to permit the practically continuous flow of metal into the mold, for otherwise a transverse fissure, termed a "stop pour," may readily result.

Pouring may be either from the bottom (through a refractory-lined conduit alongside the mold, communicating with similar passages in the mold bottom and its cover plate, on top of which the ingot is cast) or from the top (usually through a small intermediate ladle called a head box, the function of which is to remove the velocity head of the stream due to the height of the metal in the ladle). The first method exposes the metal less to oxidation and gives cleaner surfaces, but may introduce slag if the runner bricks are eroded by the steel. The second method exposes the metal more and gives poorer surfaces because there will inevitably be some splash congealed on the sides of the mold, but it introduces the minimum of fluxed refractories.

The ingot mold may be round and of sand, as was that for this emergency 114-in. ingot of 375,000 lb., but for most purposes this is not desirable because the slow cooling of an ingot cast in sand induces the formation of very large crystals, requiring

[1] Assistant to President, The Midvale Company. Mem. A.S.M.E. Mr. Cox was born in Philadelphia in 1866. He was educated in private schools, receiving finally the degree of Mechanical Engineer from the Stevens Institute of Technology in 1887. In 1888 he entered the service of the Midvale Steel Company, with which company or its successors he has continued, having been in charge of the forge, armor, projectile, and research departments, and is now Assistant to the President. Mr. Cox has taken out patents on armor plate, projectiles, and alloy steels, and is the author of various technical papers, as well as the article on recommended practice for large forgings in the National Metal Handbook of the American Society for Steel Treating.

Presented at the Fourth National Iron and Steel Meeting, Chicago, Ill., September 24 to 26, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

more heat, or more time at heat, or more forging, or treatment, to produce as fine a final grain as would have resulted had the ingot been cast in an iron mold, as was this 108-in. octagon ingot of 455,000 lb.

Generally the mold is of cast iron and is an octagon or higher polygon in cross-section, rarely round. To increase the ratio of perimeter to area in the ingot, with the object of preventing its cracking through cooling contraction of the ingot skin, the sides of the ingot polygon are usually made concave, with small corner radii, or are crenate. The walls of the mold are thick, so as to chill a thick skin on the ingot, which will not be burst by ferrostatic pressure from above when the ingot shrinks from the mold and loses its support.

Sufficient taper is given the mold to enable the ingot readily to be stripped, the amount varying from about $^1/_8$ to $^3/_8$ in. in

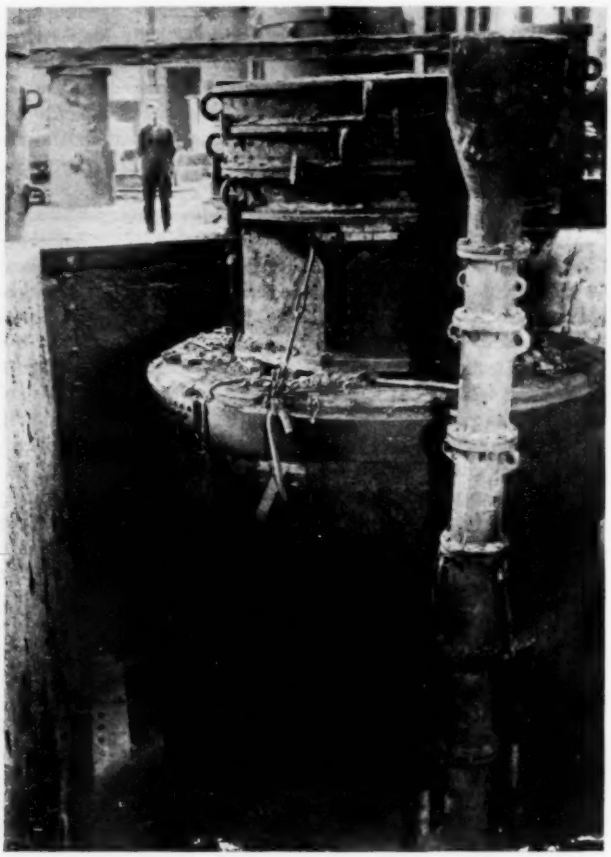

FIG. 1 MOLD FOR BOTTOM POURING

diameter per foot of length, and the inner surface is carefully coated with a mold wash.

The ingot may be cast with the large end up or down, but the best practice is to cast it large end up, as there is then a natural tendency for solidification to proceed regularly from the bottom upward. At the upper end of the mold is fitted a refractory-lined sink head in which the metal cools more slowly than in the chilling mold and remains fluid to feed the pipe caused by the contraction accompanying solidification of the steel in the ingot body. Toward it also gravitate the non-metallic impurities unavoidably present in the steel. We have tested scores of heats while in the electric furnace and found them perfectly clean, but every one showed foreign matter when examined in the ingot.

The proportion of the total ingot weight contained in the sinkhead varies with the design of the mold, the character of the metal, and its ultimate use. For the usual run of cylinder ingots, cast in heavy iron molds, a sinkhead of 15 per cent will suffice.

If the ingot be cast small end up, every precaution must be taken to feed the shrinkage or there will be in the upper end a

FIG. 2 POURING A LARGE INGOT

central internal void called a pipe. It may result from too small or too light a sinkhead or from an improperly designed mold. For a hollow forging this might be thought unobjectionable but it is not, because a concentration of impurities occurs around and immediately below the pipe which might not be entirely removed subsequently and should therefore be avoided.

Much judgment is required in pouring large ingots, to avoid cracking by too fast pouring or bad surfaces by too slow pouring.

When the mold has been filled, the upper surface of the metal in the sinkhead is covered with an insulating material, usually sand, to delay solidification, and under certain circumstances it may be necessary, after some hours, to bring up fresh metal to fill the shrinkage which has taken place.

After casting, the ingot may be stripped in a few hours if poured small end up, but must solidify much more thoroughly before it can be lifted from the mold when poured big end up. In both cases it must remain vertical until completely solidified throughout, or a pipe will result. It is our custom to allow a 63-in. ingot to stand from 12 to 15 hours before throwing it down, an 82-in. ingot about 20 hours, and a 108-in. ingot from 40 to 48 hours.

Very large ingots contain such great internal stresses, and the initial heat is so valuable, that it is highly inadvisable to allow them to cool unduly before charging them into the forge furnace. Even to anneal them for decapitating and boring when cold is dangerous, although for medium size ingots it is often done, particularly abroad. In such cases it is generally advisable to anneal the ingots before allowing them to go cold.

At first sight it might be thought a good plan to cast hollow ingots for hollow forgings, such as the 78-in. one shown, but practical experience has not been satisfactory with large hollow ingots. The cylindrical shrinkage weakness is always present in the wall, and it is most difficult to avoid scabs on the interior

surface; yet this system has been followed in some cases, as in medium-size ingots for hoops for the Swedish artillery, because of its cheapness.

The forge furnace is generally of the movable-hearth type for very heavy ingots intended for cylinders. It may be oil- or gas-fired or may use powdered coal for fuel. In it the ingot is slowly and carefully brought up to a forging heat in the course of many hours, approximately an hour to the inch of diameter,

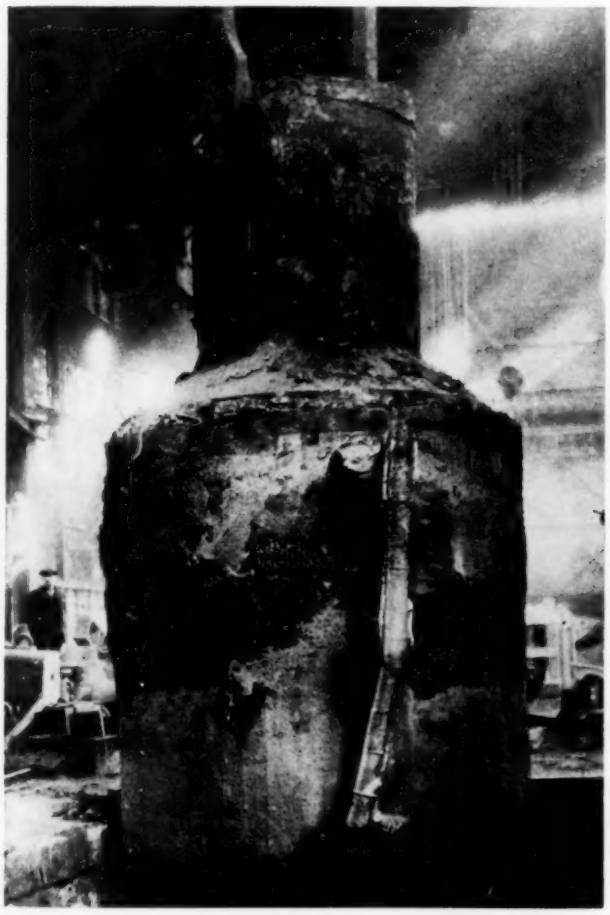

FIG. 3 SAND-CAST 114-IN. INGOT OF 375,000 LB.

and is then thoroughly soaked until every part is fully up to the desired temperature. It is advisable to heat the metal at first as highly as its composition will allow without injury, for a high temperature hastens the solution of the ingot structure—a much finer grain resulting when the metal finally cools than would follow were the temperature too low.

After a sufficient heating, the usual temperature for low-carbon steel being about 2200 to 2250 deg. fahr., the ingot is removed from the furnace, placed under a powerful hydraulic press, and the sinkhead sliced off with a large cutter.

The block is then reheated thoroughly, stood on end under the press, and upset to a convenient length for punching, the extent depending chiefly on the vertical clearance of the press. This upsetting requires more power than any other press operation except forging thin plates. Thus, to upset a block averaging 7 ft. $7^3/_8$ in. in diameter and 11 ft. 1 in. long to 8 ft. 11 in. in median diameter by 7 ft. 3 in. long (i.e., about $7^1/_2$ ft. by 11 ft. to 9 ft. by 7 ft.), requires 7000 tons, an average pressure of 1560 lb per sq. in. on the median area. The pressure required rises rapidly with decrease in thickness, the internal friction being greater the thinner the piece. Thus to reduce a block 30 in. in diameter by $7^3/_{16}$ in. thick to 42 in. diameter by 4 in. thick requires a pressure of 8100 lb. per sq. in. over five times as much.

After reheating, the upset block is next punched or trephined with a hole about 24 in. in diameter. This hole is generally enlarged by a drift to about 27 in. in diameter, to admit using a stiffer mandrel for the expending operation later on.

If at this stage the diameter of the piece be considerable compared with its length, it is usual to draw out the billet on a mandrel between plain dies, or by the press crossheads if too large to admit of using dies, until of a length that is slightly shorter than the bottom crosshead, and of a diameter small enough to permit expansion of the bore to 3 or 4 in. larger than the largest mandrel to be used in the final forging, for the longer the piece the more easily it is kept from going long-cornered.

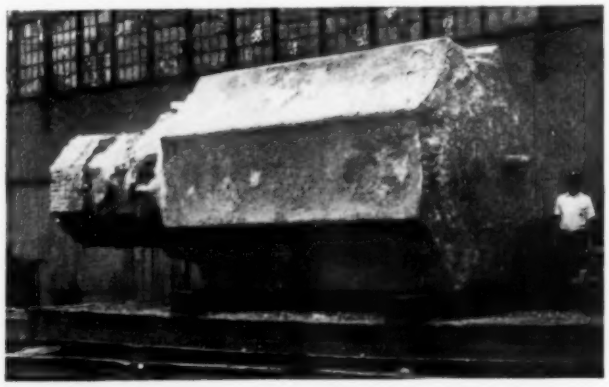

FIG. 4 AN 108-IN. OCTAGON INGOT OF 455,000 LB.

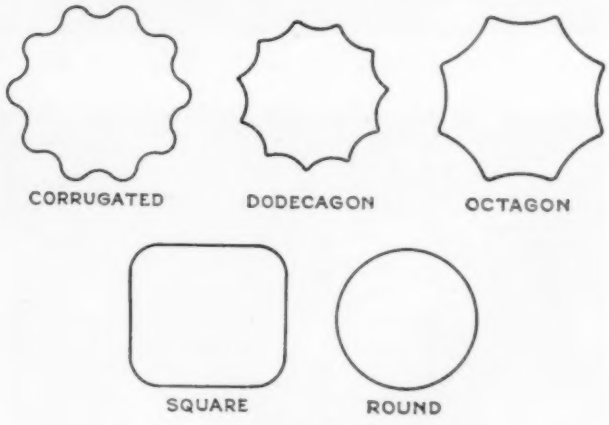

FIG. 5 INGOT CROSS-SECTIONS

The largest mandrel in use in the United States today is about 72 in. in diameter.

Drawn to a sufficient length, the billet is swung on a mandrel supported at each end close to it upon the bottom crosshead of the press, and the hole is enlarged by a narrow-faced top die parallel to the mandrel, which thins the walls without sensibly increasing their length, the billet being revolved on its axis through a small angle after each press stroke. Since there is almost no longitudinal flow of metal, the diameter of the hole rapidly increases as the walls are thinned, until the desired internal diameter has been reached.

After the press dies have been changed to a bottom vee die

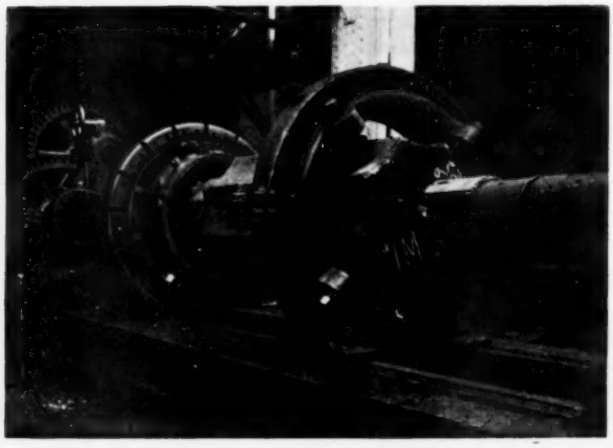

FIG. 6 BORING AN INGOT

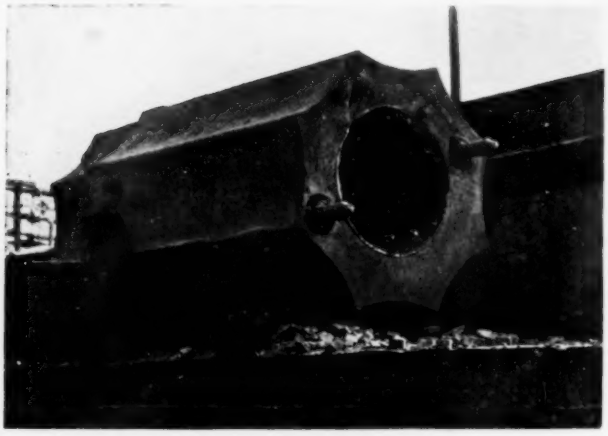

FIG. 7 HOLLOW-CAST INGOT, 78 IN. OCTAGON

FIG. 8 CAR-BOTTOM FORGE FURNACE WITH 108-IN. INGOT

and a short plain-top die of the same width, a slightly tapered mandrel is inserted in the reheated billet and the bore is slightly reduced by forging, so as to crack the scale, which if left in the bore would tend to key the mandrel fast and prevent its withdrawal. After the scale has been raked out, the mandrel is reinserted and forging is begun with heavy pressure, which closes the walls of the billet down upon the mandrel and then reduces their thickness. Confined circumferentially between the three die faces and the mandrel, the metal flows longitudinally as the exterior diameter is reduced. The whole forging is thus roughed down until it is of such diameter that it is possible to bring a short section at mid-length to the final forged diameter in one heat. This having been done, first one end and then the other is brought to final sizes, as many heats being taken as the length of the piece may require.

For the finishing operations a furnace with fixed bottom is

FIG. 9 PUNCHING A LARGE BLOCK

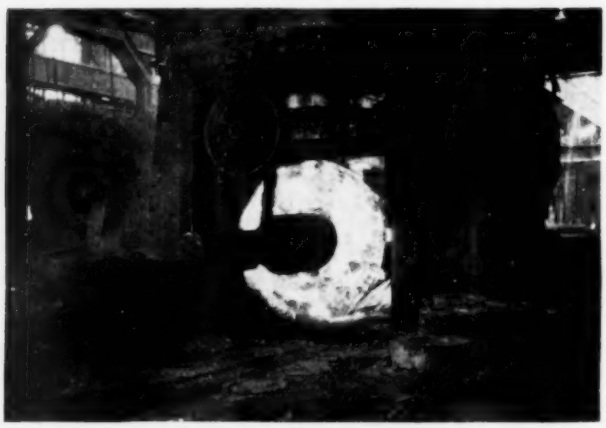

FIG. 10 ROUGHING ON MANDREL ON PLAIN DIES

desirable. Into it, after each heat, there is inserted as much of the end of the forging as remains unfinished. As in every heating, before a piece is removed from the furnace for forging it is turned upside down and soaked for a while, to allow the colder bottom side to equalize in temperature. Were this not done, the hole would quickly get out of center. It is usual, also, when the piece is inverted, to push into the furnace a little of the finished section. It is not there long enough to be injuriously affected by the heat, and the step avoids too sudden changes of temperature in the forging.

In certain cases of especially sensitive steels it may be necessary to avoid complete cooling of any part of a forging before it has received its preliminary annealing.

The angle between the faces of bottom vee dies varies from about 105 to about 120 deg. A large angle makes easier the removal of the mandrel after each heat and permits the making of a greater range of diameters in one die, but has the disadvantage of increasing the arcs between the top die and the sides of the vee. The longer these arcs the greater is the tendency of the unsupported wall of the forging not to shorten but to spring away from the mandrel and form a peak which, in turn, has to be pressed back into contact with the mandrel before the next reduction in wall thickness can be made. It is for this reason that, as the internal diameters of forged cylinders increase, the wall thickness must be increased, to control the "breathing" in the vee dies. An attempt to forge a cylinder

too thin for its diameter might require so many reheatings that the loss by scaling would exceed the saving in weight of thinner walls, and a short forging would result.

At each end of the forging there is left a greater or less length of enlarged outer diameter, to provide metal for the closure of the finished vessel, the length and diameter depending on the type of closure. A head to be attached by studs, or by bolts through a flange, requires but a short section of sufficient diameter, but if the vessel is to be closed in under the press there must be provided enough metal to allow for the final thickness required

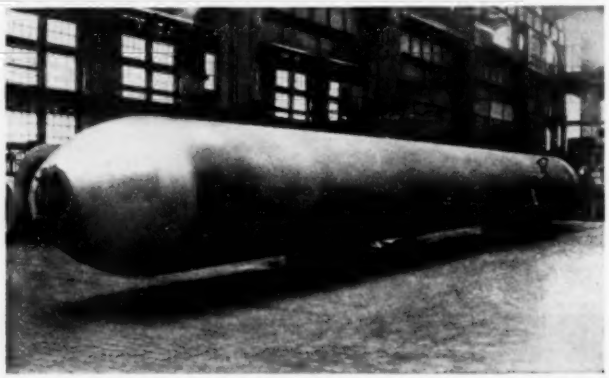

FIG. 28 BOILER DRUM WITH CIRCULAR MANHOLE

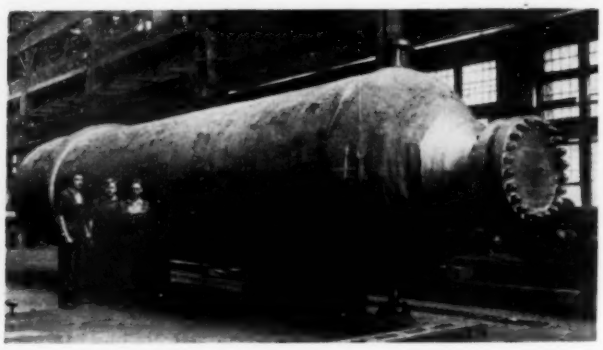

FIG. 29 FLANGED END WITH BOLTED COVER

as well as for the unavoidable elongation accompanying the operation.

This stage of the forging finished, the cylinder is generally given an annealing above the upper critical temperature of its composition, to refine the grain and relieve stresses or to secure the physical properties desired.

From the annealing furnace the cylinder goes next to the machine shop, where, if required, test pieces are cut from it to determine its physical properties. If so ordered, it is rough- or finish-bored, the first operation being performed by tools set in the ends of the arms of a spider fed along a heavy stationary boring bar, the forging being revolved in a lathe. Finish-boring is generally done by two cutters at opposite diameters of a wood- or babbitt-packed skeleton steel bit carried in a socket in the end of a heavy boring bar which is fed into the forging as it revolves in a lathe.

Such exterior work as is required on the cylinder is done now. The body may be rough- or smooth-turned, supporting rings cut from thicker bands left on the exterior at the press, and if the ends of the cylinder are to be closed in, the outside of the heavy collars left at the ends is contoured to give the amount and distribution of metal that calculation, guided by experience, shows to be necessary to secure the final shape and dimensions desired. In this work, using heavy tools of high-speed steel, one can take a cut of from 1 in. to $1^1/_4$ in. depth, with a feed of $^1/_4$ in., at about 20 to 25 ft. per minute on a simple mild steel.

The allowance for machining depends somewhat upon the internal diameter. Since it is impossible to make the work hug a large mandrel as snugly as a small one, there is, in large cylinders, a greater probability of pockets existing in the bore, places where the metal has stood off the mandrel, leaving the bore large. Generally, 1 in. on a side, inside and out, is sufficient allowance for machining a large cylinder.

After the ends have been contoured they are reheated and closed in to measure or to templet, in suitable dies. The operation requires much skill and may be very troublesome. If conditions are not exactly right, as the bore decreases, wrinkles first form in the mouth of the forging, and then the sides of the wrinkles close together, forming galls. If closing-in continues, the galls quickly turn into deep splits. If these galls occur, before they have progressed too far they must be removed by boring after the forging has cooled, and the work of closing in is then resumed.

If the cylinder be a boiler drum, after closing-in it is required

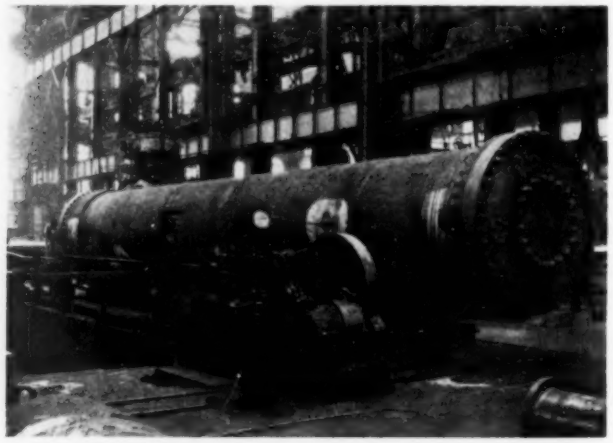

FIG. 30 HYDROSTATIC TEST

to be reannealed all over at a temperature above the upper critical point, but below the temperature of its first annealing, so as not to affect the physical properties already determined. If the physical properties demanded require quenching and tempering of the forging, the necessary treatment is now given, but it is generally considered better to attain these properties by annealing or by free-cooling in air, from a quenching temperature, followed, or not, by a light tempering to release stresses.

Very large vessels are beyond the capacity of any quenching plant in existence, which limits the possibilities of that process; slower cooling avoids a certain amount of risk always present in quenching; and, finally, as operating temperatures rise, the increased hot strength gained by quenching gradually disappears, beginning at about 750 deg. fahr. (400 deg. cent.), and is gone at about 1050 deg. fahr. (570 deg. cent.) for all but special alloy steels.

If it be a chemical vessel, it is usual to take the tests at this stage, when all heating steps have ended. Tests are generally longitudinal tensile bars, of standard size, 0.505 in. in diameter by 2 in. gage length, which must show the physical properties required by the specifications. Occasionally, transverse bending tests are desired, rectangular bars usually 1 in. by $^1/_2$ in. which are customarily required to bend cold through 180 deg. around a pin of diameter equal to twice the thickness of the

FIG. 31 SHIPPING THE LARGE CYLINDERS

bar without cracking of the convex surface of the bent portion.

The closed-in ends are now machined on the exterior to the extent that may be necessary, the throat is opened to final diameter, and always there is the machining of the closure.

The percentage of the shipped weight to ingot weight in large cylinders depends upon the design and the amount of machining required, varying from about 55 per cent for cylinders rough-forged in bore and exterior to about 35 per cent for those finished all over.

Cylinders may have their ends closed by a variety of methods. A row of studs may be implanted in the end face to attach a head with a joint-making gasket, generally a copper ring, or a flange may be turned up at the end of the cylinder so as to allow fitting of through-bolts to hold the head, which may be of many shapes. Sometimes a screw thread is cut in the interior of the cylinder mouth, either continuous or interrupted, and a corresponding plug fitted which carried an obturating device selected from a number available. The choice of continuous or interrupted thread depends chiefly on the frequency with which it will be necessary to open the cylinder when put in service.

If a full-size or approximately full-size opening into the cylinder be not necessary or desirable, a reducing section can be attached or made integrally by closing in the mouth of the cylinder. Boiler drums of this type may have the ends closed in to take the usual elliptical manhole cover, or, as has been done frequently of late, one or both of the covers may be circular—a much cheaper form. In case both covers are circular it is necessary to finish them completely and build them into a wall in the middle of the drum where they can be protected from oxidation when the drum is heated at each end for closing in, and heated all over for final annealing, after which the seats are finished. Sometimes an end of the closed-in cylinder is sealed by a conical fitting, or the neck may be flanged and provided with a bolted cover fitted over a ground-steel gasket plate.

Any lateral fittings desired are attached, and after a thorough inspection for dimensions a final pressure test is applied to the sealed cylinder, water being pumped into it until the desired test pressure is reached, usually $1^1/_2$ times the working pressure. Search is then made for any leaks that may require tightening of bolts or refitting of gaskets, adjustments being made until all points are watertight. If required, air may be pumped in up to specified pressure and any fall of pressure over a given time be noted. Where this is not necessary it is to be avoided, being a much more costly test than the hydrostatic.

With damageable parts protected by lagging, the finished cylinder is loaded in cradles on one of the special cars now provided by the railroads for this type of heavy service, secured in position by holding-down bolts, and sent out to perform the service for which it was designed and built.

Discussion

P. E. MCKINNEY.[2] This excellent paper is so complete that it is difficult to add anything of interest to what has been presented. The author touches on the use of riveted or welded vessels for certain applications. The production of large pressure vessels from plates formed and welded, both of carbon and alloy steels, is developing at an astounding rate, and it can safely be predicted that within the next few years this type of construction will find ever-widening application.

While the fact remains that fusion welds are essentially cast metal joints, improvements in welding materials and standardization of welding practice have eliminated many of the objectionable characteristics of welding which formerly were considered inherent.

Notwithstanding the broadening of applications for vessels of welded construction, the ever-increasing demand of industries for vessels to operate at higher temperatures and pressures creates a very wide field in which the use of vessels of weldless forged-steel construction is absolutely essential. One can look forward to these more exacting service conditions requiring the development of large alloy-steel forgings with characteristics which are beyond anything that has been contemplated in the past.

The author refers to the importance of steel-making practice in the production of good cylinders, which is a point that cannot be too strongly emphasized. In the melting of steel for these large forgings, refinement must be carried to a point which would not be

[2] Bethlehem Steel Company, Bethlehem, Pa.

justifiable or necessary in the production of small or medium size forgings. Large masses of molten metal, slowly solidifying, would react in the mold unless the steel is in a condition approximating equilibrium. Refining and finishing to such a degree that the steel can be left in the furnace for at least an hour

FIG. 34 POURING OF 108-IN. INGOT MOLD, SHOWING THE THREE LADLES IN PLACE, SPECIAL RUNNERS, AND LIFTING EQUIPMENT

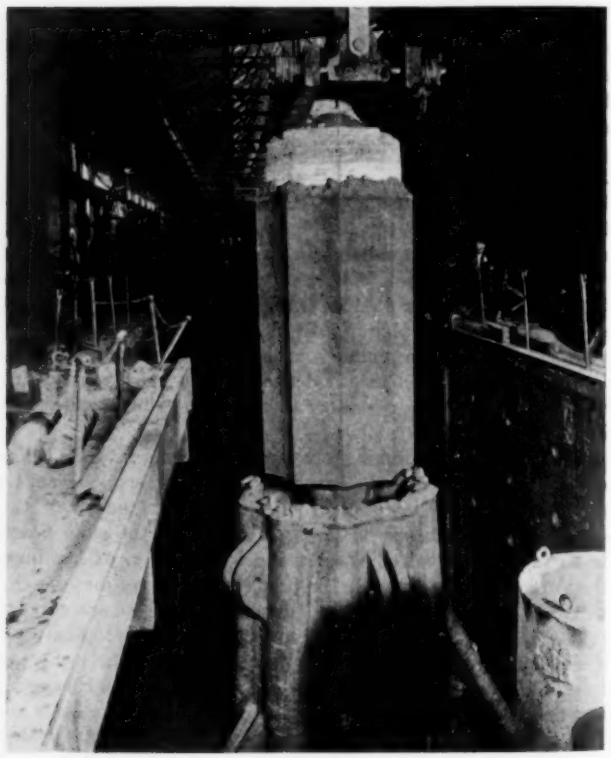

FIG. 35 REMOVING 108-IN. INGOT FROM MOLD; WEIGHT OF INGOT, 427,000 LB.

with practically no action or change in composition, is necessary for the successful production of this type of material. This involves a most careful study of slags, temperatures, and all other conditions surrounding the production of the molten steel.

One outstanding advantage of seamless forged vessels is that during the forging operation the material gets a very thorough proof test as to its soundness and malleability. The forging operations, involving as they do the upsetting, enlarging, piercing, and, finally, drawing down from a wall thickness of approximately 50 in. to approximately $6^1/_2$ in., would uncover any unsound areas in the material, and it is reasonably certain that a mass of metal which will stand these operations without breaking up or showing serious tears is sound and homogeneous throughout.

In the handling of these massive forgings, many extraordinary hazards are encountered, and the entire forging may be spoiled by a mistake in any one of the many operations, such as:

(1) Pouring of the ingot, involving the getting of a number of open-hearth heats in perfect condition for pouring at one time

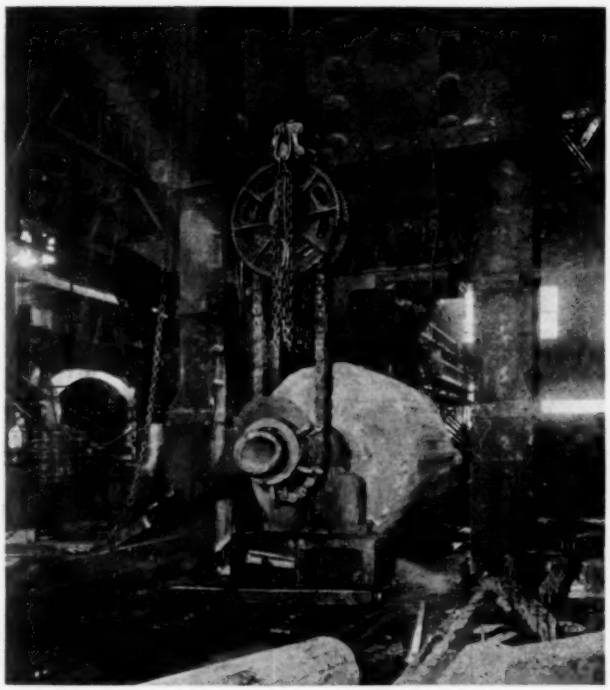

FIG. 36 ENLARGING OPERATION, SHOWING RIGGING FOR REVOLVING THE MANDREL

(2) Any one of the many forging operations involving holding this mass of metal at a forging temperature for from 14 to 16 days
(3) The heat treatment of such a large mass of steel
(4) Machining operations in which the improper drilling of holes or machining of header seats may render the forging unsatisfactory for the purpose intended.

A matter which should be of considerable interest to mechanical engineers is the magnitude of the special equipment, other than furnaces, machinery, and cranes, required in the production of these large forgings.

With the admitted superiority of chilled cast ingots over sand cast ingots, the first problem presented to the steelmaker is the production of a large enough mold to cast these massive ingots. The casting of these large molds requires, in turn, special heavy flask equipment, special clamping devices, patterns, and core-box equipment. The large molds are cast either from molten metal transferred from the blast furnace in heavy mixer ladles or from pig iron remelted in the open-hearth furnace. The mold required for casting a 108-in. corrugated ingot weighs approximately 360,000 lb., the base stool for the mold weighs approximately 86,000 lb., and the sink-head flask weighs approximately 40,000 lb. without the refractory lining. This mold equipment will usually not withstand the pouring of more than 15 ingots without renewal. Innumerable heavy mandrels and special tools are

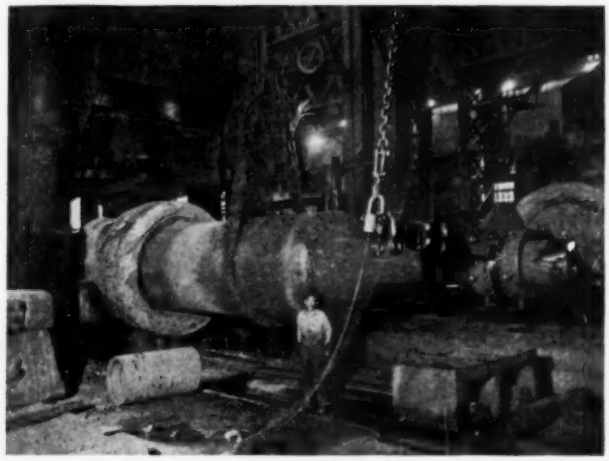

FIG. 37 OPERATION OF DRAWING TO LENGTH ON MANDREL

FIG. 38 ROUGH FORGING, SHOWING LIFTING GEAR

FIG. 39 FORGINGS IN COMPLETED FORM AS TANKS ON HELIUM TANK CAR

required for the various forging operations other than the conventional tool equipment required for hydraulic presses. As an instance, one of the large mandrels required in the production of oil-still forgings is approximately 58 in. diameter by 22 ft. long and weighs 210,000 lb. For this forging, there is required a 91-in. ingot weighing 300,000 lb. In many cases these mandrels will not withstand more than 8 to 10 forging operations.

Notwithstanding the massive sizes of these forgings and the many hazards involved in their production, the steel industry has so surrounded the various operations with safeguards and precautions to assure quality that it is quite apparent that, for the most exacting applications, this type of construction now holds a position which cannot justify substitution for it of any other process.

Continuous Reheating Furnaces for Rolling Mills

By A. L. CULBERTSON,[1] PITTSBURGH, PA.

The subject of this paper is one which is indeed much broader than could be expected from a casual glance, due to the many types of furnaces used for the various rolling-mill operations. The subject matter is confined to those furnaces used for reheating purposes, necessary for serving, rolling, and piercing mills. Even this reduced field leaves it an extremely broad one when considering the types of furnaces required for the different operations.

The author discusses the various classes, using only broad subdivisions of each, and with this in mind a chart is given to show this classification, in order to permit of some common points of comparison, both as to design and operation.

CONTINUOUS reheating furnaces for rolling mills as shown in Fig. 1 are first divided into three general classifications: (1) Wide furnaces, 25 ft. to 60 ft. wide inside, (2) medium-width furnaces, 8 ft. to 25 ft. inside, and (3) narrow furnaces, 4 ft. to 8 ft. wide inside. The majority of furnaces will be found in the medium class. The three divisions as to width have been made so that general comparisons of fuel consumptions and tonnage outputs among a number of furnaces may be confined to the class in which they are given. This is desirable as a means of maintaining accuracy in comparison.

It is known that the wide furnace operates on much less fuel per ton than a medium-width furnace of the same design, and, likewise, a medium-width furnace uses less fuel than a similar narrow furnace. Heating capacity is likewise a function of the width of the furnace.

Wide Furnaces

These are generally used for heating light sections, such as flats or squares with a thickness of material very seldom more than 3 in. and frequently as thin as $1\frac{1}{2}$ in. Inasmuch as the distance is limited through which these light sections may be pushed without having buckling, the length is limited. Should these furnaces be provided with a horizontal hearth, the friction would be greatest and the length a minimum. In an effort to overcome friction and make it possible to lengthen the furnace, a sloping hearth is used with the material being pushed downhill. Due to the lightness of the material, it is not desirable to use underfiring. This class of furnace, therefore, generally employs top-firing only with the material passing through the furnace either on solid billets used as skids embedded in the hearth or being pushed over the refractory hearth without any skids whatsoever.

The use of solid skids in top-fired furnaces is desirable to reduce the wearing away of refractories. Since the steel completely covers the hearth, it prevents the direct action of the flame upon the skids, and a fairly long life is obtained. Solid skids, when used, extend from the charging door of the furnace down to that point where the temperatures become high enough that rapid wearing away of the skids is evidenced. From this point, the usual construction of the hearth calls for a chrome-ore facing which is quite effective in withstanding the abrasive action of the material passing over it.

With the length of the furnace limited, the next method employed in increasing the tonnage output is widening of the furnace that longer billets may be charged.

The tonnage output of any furnace is dependent upon the heat-absorbing surface of the steel exposed to the heat. By widening the furnace, the billets may be lengthened and the heat-absorbing surface increased, thus increasing the tonnage obtained from the furnace. The most common size of furnace in this class employs billets 30 ft. in length. Depending upon the thickness of material, its physical shape, i.e., squareness of corners and straightness, tonnages have been obtained of from 25 to 75 tons per hour, depending upon the length possible to push the billets and the temperatures carried throughout. The wide furnace is usually used in connection with a continuous mill with but one furnace serving the mill. The small section of material heated eliminates the possibility of using it as an end-discharged furnace. These furnaces are, therefore, discharged through the side directly into the first pass of the mill, the material being pushed out by means of pinch roll and pusher bar operated from the side opposite the mill. This type of furnace could be end charged, but to do so would reduce the tonnage output, since the distance the material can be pushed is the limiting factor. As a result, they are charged through the side, employing cantilevered water-cooled rolls within the furnace proper, extending through the back wall through which the pusher also works, or else by means of a skid trough on which the material is pushed in a similar manner to that employed in discharging the furnace.

The fuel consumption of wide furnaces is extremely low per ton of output. This is true whether preheated air for combustion is employed or not, the reason for this low fuel consumption being:

1 Continuity of operation. The furnace is usually being pushed at top speed serving a continuous mill. Yearly figures on operation of a number of these furnaces show an operating time of 90 per cent to 98 per cent of that possible.

2 The furnaces are side charged and side discharged. This

[1] Manager, Furnace Division, Rust Engineering Co. Mr. Culbertson was born in Mt. Vernon, Ohio, on May 25, 1895. He has the Bachelor Chemistry degree from Cornell University, after having attended Mt. Vernon High School, Ohio State University, and Cornell University, and doing post-graduate work and teaching chemistry at Cornell University. Mr. Culbertson conducted research in chemistry in 1917, E. I. du Pont de Nemours Co.; was Ensign Naval Aviation Pilot Instructor at Key West Naval Air Station, 1918–1919; was with Chapman Engineering Company as operation engineer and salesman, 1919 and 1920; foreign representative, Chapman Engineering Company, in charge of design, sales, operation tests, etc., in England and France, 1920 and 1921. He was Vice-President and Assistant General Manager of Chapman Engineering Company and Chapman Stein Furnace Company, 1921 to 1927, designing, sales, and construction of gas producers and industrial furnaces. From 1927 to the present he has been in his present association.

Presented at the Fourth National Iron and Steel Meeting, Chicago, Ill., Sept. 24 to 26, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

method of charging and discharging makes it possible to close up the entire furnace excepting a small opening at the charging and discharging points. This effectively eliminates the influx of cold air usually found at both ends of an end-discharged furnace. Cold-air infiltration not only chills the furnace but likewise chills the flame, eliminating the high temperature radiation heat-transfer possibilities. It also causes oxidation and higher fuel cost. Eliminating these disadvantages results in the saving of from 30 to 50 lb. of coal or its equivalent per ton of steel heated. Unfortunately, all furnaces cannot be constructed of side-discharge design, due to the operation requiring more than one furnace.

3 A wide furnace makes possible a reduced fuel cost by its very width. In comparing two furnaces heating 15-ft. billets with one furnace heating 30-ft. billets, it is readily seen that two side walls and several feet of hearth and roof together with their radiation losses, have been eliminated. In other words, the wider the furnace the less the fuel consumption due to the reduced amount of radiating surface which loses heat to the atmosphere. This results in a saving of from 10 to 30 lb. of coal per ton according to the width of the furnace.

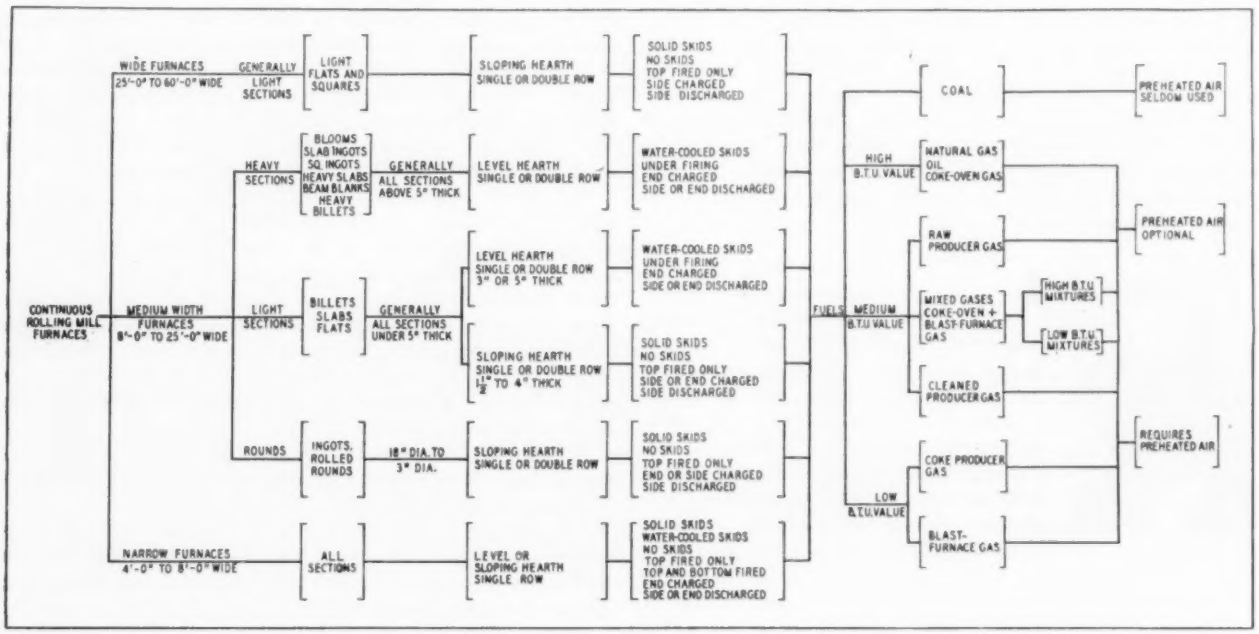

FIG. 1 CLASSIFICATION OF ROLLING-MILL FURNACES

MEDIUM-WIDTH FURNACES

As will be seen on the chart, this class of furnaces is used for more purposes than either the wide or narrow classes. Medium-width furnaces are subdivided into three classifications, those heating (1) heavy sections, (2) light sections, and (3) rounds.

Discussing them in the above order, it is found that the heavy section classification contains furnaces that heat blooms, slab ingots, square ingots, heavy slabs, beam blanks, and heavy billets. The material to be heated in this classification is 5 in. in thickness and over. Continuous furnaces operate successfully heating blooms 13 in. square; slab ingots 12 in. by 30 in. by 48 in; square ingots up to 18 in.; heavy slabs as used for plate mills and strip sheet mills; large beam blanks; and heavy billets for any general use.

In general, furnaces heating these heavy sections require "underheating" as well as "topheating." This necessitates the use of watercooled skid pipes in order that underfiring may be accomplished. Ordinarily, the hearth is level and the furnace is provided with a refractory hearth at the discharge end in order to eliminate the effect of the watercooled skid pipes and permit equalization of temperature before discharging. Occasionally, no hearth is used and some form of skid shoe is used on top of the watercooled skids to raise the material far enough from the skid to likewise eliminate the cooling effect. Both of these methods are in use and the object of their use is identical; viz., to make it possible that the material being discharged leave the furnace at an uniform temperature throughout with no objectionable black spots.

Heavy sections make it possible to increase the pushing length. This type furnace is, therefore, end charged. Either side or end discharging may be employed, although end discharging is the more common. When furnaces are side discharged, it is usual to employ a discharging machine which may be equipped either with tongs or peel. This machine makes it possible to space the heavy pieces on the refractory hearth, if desired, and possibly turn them over for a further equalization of temperature if the design of furnace makes it essential. It is desirable to lift the material before discharging in order to reduce hearth maintenance when side discharging.

Either single or double row may be charged. The average size for this type of furnace approximates 15 to 20 ft. in width and 50 to 60 ft. in length.

Due to the heavy sections, the use of watercooled skids is required. This, of necessity, increases the fuel consumption since the cooling water will usually take away in heat units the B.t.u. equivalent of from 30 to 50 lb. of coal per ton.

It has been found that end discharging saves an appreciable amount of labor and equipment. It is also a saver of space in rolling mills. End discharging makes it possible to serve a mill with a number of furnaces spaced closely together since the necessity of a manipulating machine for discharging is eliminated. This feature makes it possible to keep the size of the furnaces within reasonable constructional limits and vary the tonnage of the mill by the number of furnaces being used. Often a mill is called upon to roll a variety of sizes and with its capacity being mainly determined as to the number of pieces per hour that it can handle, the number of furnaces employed to serve it will vary in accordance with the size of the material being heated, so that a mill may be kept busy as much of the time as is possible.

End discharging saves in labor and space, but in itself usually requires more fuel than the side-discharge type of furnace. Referring to the old standard type of end-discharge furnace equipped for firing above the steel only at the discharge point, this difference in fuel consumption amounts to 40 to 50 lb. of coal per ton over the old side-discharge type. This is due partly to the fact that the discharge door is usually of the flapper type which does not make a tight closure. Since gravity discharge is employed, a natural chimney effect is found at the discharge slope and causes infiltration of a large quantity of cold air. This cold air not only causes oxidation but chills the material in the furnace at its point of discharge. It furthermore chills the flame and reduces the rate of heat transfer which is so beneficial if properly applied.

Rounds

The furnaces used for heating rounds for piercing mills usually employ a sloping hearth of varying degree in accordance with the size of material to be heated, the method of working the material through the furnace, and its nature. The usual slope employed is 1 in. to $1^1/_2$ in. per foot. Rounds are heated from 3 in. to 18 in. in diameter, the larger sizes being in the form of cast ingots, with the smaller sizes being rolled and hot sawed. The smaller size rounds are usually rolled through the furnace by hand with a large number of doors either rolling type or lift type, being available so that the operators may reach the entire hearth.

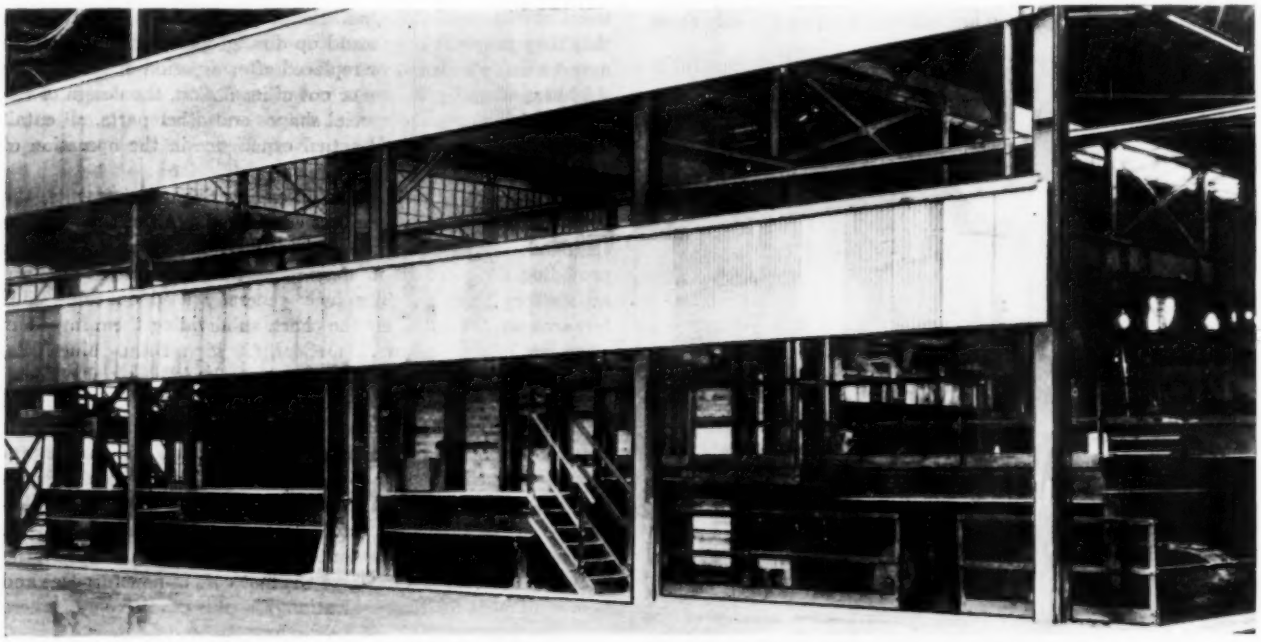

Fig. 2 Three Furnaces at the Republic Steel Corporation, Youngstown, Ohio, Using Producer Gas or Coke-Oven Gas

Light Sections

Under this classification come those furnaces of medium width which are confined to heating sections up to 5 in. in thickness, generally billets, thin slabs, and flats. A level hearth is usually employed for the slabs and billets from 3 in. to 5 in. thickness with a sloping hearth employed for the thinner sections, for the same reasons as mentioned under the wide furnaces above. Those furnaces with a level hearth usually employ watercooled skids and should be underfired. They are end charged and may be either side or end discharged. If single rows are used and the tonnage of the mill is not excessive, side discharging is generally employed. When double rows are employed and the capacity of the mill requires more than one furnace, end discharging is usual.

For the sloping-hearth type, solid skids or no skids at all are the custom, with topfiring only employed, since underfiring is undesirable with the thinner sections. Either side or end-charging may be used, side discharging, however, being the usual practice.

As in the case with furnaces for heavy sections, watercooled skid pipes and end discharging requires additional fuel, but less labor, whereas the side-discharged furnace with sloping hearth and no watercooled skids is economical from a fuel standpoint but higher in labor.

For the larger size rounds, a manipulating machine usually works the rounds through the furnace, thus saving labor.

Furnaces heating rounds are usually side discharged. This is desirable in order to maintain the discharging end of the furnace as nearly uniform in temperature as possible, since properly to pierce a billet concentrically, necessitates absolute uniformity of heating throughout the material. Even with side discharging, this class of furnace has a high fuel consumption due mainly to the low temperatures carried, the amount of hearth which is not covered, and last, but quite important, the number of openings required in the furnace side walls for rolling the material through the furnace. Very seldom does the furnace operator take care that these doors be closed when not being used. As a result the general chilling of the furnace by infiltrated air increases the fuel consumption. Figures of 200 to 250 lb. of coal per ton are the rule rather than exception, and often it has been known to go as high as 350 to 400 lb. of coal.

Narrow Furnaces

Under this classification come furnaces 4 to 8 ft. in width. They are used to heat all kinds of sections; rounds, flats, billets, blooms, etc. This type furnace may have level or sloping hearth, but usually only takes one row. The method of charging is determined the same as the medium-width furnaces, as likewise are the skid requirements and the methods of firing. This type of furnace is usually used for small mills where production is not

high or where a variety of products rule, in which case a number of the single-row furnaces are used to separate orders.

When serving a piercing mill with the larger sizes, a single row is desirable from the manipulating-machine standpoint. Furnaces 130 ft. in length have been constructed, although the usual size would be from 50 to 70 ft.

Combustion Engineering and Fuel Requirements

In the preceding description of wide, medium, and narrow furnaces, only general characteristics have been described. No reference was made to the fuel to be employed nor was reference made to preheated air. The reason for this is that mill requirements and the material to be heated should determine only those

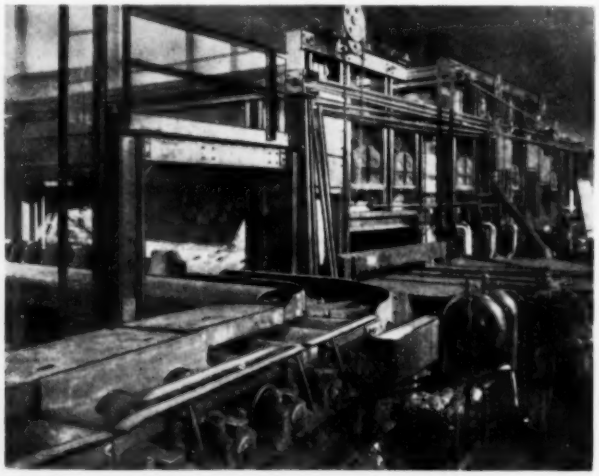

Fig. 3 Furnace at the Washburn Wire Company Fired With Fuel Oil and Using Cold Air for Combustion

characteristics already described, which consist mainly of the general shape of the furnace, the method of charging and discharging, the tonnage required, space available, and the shape of the hearth. This much of the furnace can be determined with no reference to the combustion-engineering side of the question. From this point on, however, the combustion engineer enters the picture and his part is an extremely important one. It might be well at this point to express generally a thought regarding the proper design of the furnace from the furnace-builders' standpoint. In the first place, it is realized that once the shape of the furnace and general characteristics are determined in accordance with mill requirements, the remaining problem is much the greater one. The true combustion engineer looks at a furnace primarily without reference to anything excepting the holes or voids therein.

The holes in a furnace consist of ports, combustion chamber, channels, downtakes, flues, doors, etc. The areas and shapes of these holes are the most important part of a furnace and determine first of all whether the furnace will work or not, and in the second place, they determine how well it will work, both as to quality of heating and as to fuel efficiency. The combustion engineer determines the holes of the furnace and his ability is measured, not entirely with the amount of theory employed, but by the proper blending together of theory and actual operating practice in such a manner as to give best results for the problem at hand. How well he has done his work is never known until the furnace has been put into operation. If he has analyzed the problem from all the standpoints that should be taken into consideration, he has a good furnace. If some have been overlooked, it is desirable that these may be corrected with little trouble. If he has overlooked too many, the furnace is considered a failure. This is the case no matter how well the furnace has been built. It is for this reason that the holes of a furnace are looked upon as of major importance.

After the combustion engineer has determined the holes, then once more a highly important part of the furnace design has to be carried through. This entails the proper application of brick and steel work to surround the holes in such a manner as to make a furnace which will stay in operation once it has been constructed. This part of the furnace designing requires likewise a mixture of theory and practice with the proper consideration given for the temperatures carried throughout the furnace, the proper material to withstand them, and the proper method of construction that they may not only stand up during operation, but likewise may be easily repaired or replaced after a period of time. The thickness of walls, the use or not of insulation, the design of the watercooled parts, the special shapes and other parts, all entail careful consideration and actual experience in the operation of furnaces.

In considering the combustion-engineering requirements, the fuels that may be used are first considered. All of the furnaces classified in Fig. 1 operate satisfactorily on a variety of fuels providing the combustion engineering has been carried out in a satisfactory manner. The fuels generally used on continuous furnaces are tabulated on the chart, subdividing them into four classifications as follows: (1) Coal, (2) high B.t.u.-value fuels, (3) medium B.t.u.-value fuels, and (4) low B.t.u.-value fuels.

First, there is coal. It is classified by itself and may be used either by direct firing or by using stokers, although each year finds fewer continuous furnaces using this fuel. Seldom is preheated air used when coal is direct fired. This type of firing is being eliminated due to the excessive labor costs entailed which require so many points for distribution of coal and the subsequent removal of ashes, with constant attention being required from the heater. In small plants where the first cost of new furnaces and new equipment for the gasification of coal is excessive and where

Fig. 4 Double-Fired Furnace at the Steel Company of Canada Fired With Low B.T.U.-Value Mixture of Coke-Oven and Blast-Furnace Gas

no other fuel is available, coal-fired furnaces may find their place.

Second, under high B.t.u.-value fuels are natural gas, oil, and coke-oven gas.

Third, under medium B.t.u.-value fuels, are raw-producer gas, mixed gases, such as coke-oven and blast-furnace gas, and cleaned producer gas.

Fourth, low B.t.u.-value fuels contain coke producer gas and blast-furnace gas.

The reason for listing these fuels in this manner is to get a subdivision and classification, so that consideration may be given to the various groups with regard to the use of preheated air. With

coal, preheated air is seldom used. If it is used at all, it is applied above the fire bed and the fire bed is being carried in a condition approaching a semigas producer effect. Application of air beneath the grates would result in clinkering.

Preheated air is optional with natural gas, oil, coke-oven gas, raw-producer gas, or the high B.t.u. mixtures of coke-oven and blast-furnace gas. Preheated air is essential when using low B.t.u. mixtures of coke-oven and blast-furnace gas, cleaned producer gas, coke-producer gas, or blast-furnace gas.

With the higher B.t.u. fuels consideration must be given to a number of things to determine whether preheated air should be used or not. Of primary importance is the cost of the fuel delivered to the furnace per million B.t.u. In addition, consideration must be given to plant conditions, available depth, available space for the preheating equipment as well as available space for the furnace. Should a limited space only be available for the furnace, it is desirable to use preheated air to increase the temperatures and, accordingly, the tonnage output. It all sets itself up into an analysis of the existing conditions and the return which will be obtained on the added investment covering equipment to preheat the air. In recent years, a most important step has been taken in regard to the use of preheated air, and that is that the tendency is more pronounced to consider the air-preheating equipment as a separate consideration, which should stand on its own merits and be used or not in accordance with the investment value, rather than to be considered as an essential part of a furnace. This is the obvious viewpoint and the type and general design of a furnace should be decided upon which will provide maximum efficiency without regard to type of air heater to be used, and after the type of furnace is decided upon, then the preheating equipment can be properly applied whether refractory-tile recuperator, metal recuperator, or regenerative air heater, according to which one is best suited for the particular needs of the definite installation at hand. Often, the make or type may be optional. In other cases, definite types will be required.

Under the above classification of fuels and the preheated-air requirements, it will be noted that the division is made on the basis that preheated air is optional only with those fuels whose flame temperature when burned with cold air is sufficiently high to enable the proper furnace conditions to be easily obtained. The lower B.t.u.-value fuels, in some cases, will give a flame temperature which is possible to be used in continuous furnaces. As a rule they are too slow while using cold air to be a desirable fuel for satisfactory operation. The preheated-air requirements in this case are merely to obtain a B.t.u. input in the combustible mixture sufficiently high to give the desirable flame temperature and flexibility needed for proper operation in continuous-furnace work.

Continuous-Furnace Operating Requirements

After the shape and other characteristics of the furnace as described have been determined and, in addition, the fuel and its preheated-air requirements are known, the design of the furnace should be considered from the operating standpoint. In this regard, the furnace should be designed to perform the following functions which are listed in the order of their importance:

1 Uniform heat distribution throughout the mass of the discharged product at a predetermined temperature.

2 Flexibility as to tonnage output without any appreciable drop in efficiency or change in quality of heating.

3 Low oxidation losses.

4 Low furnace maintenance.

5 Low fuel consumption.

6 Ease of control.

Uniformity of Heating

The function of a continuous furnace which is of paramount importance is that heading the above list which demands "uniform heat distribution throughout the mass of the discharged product."

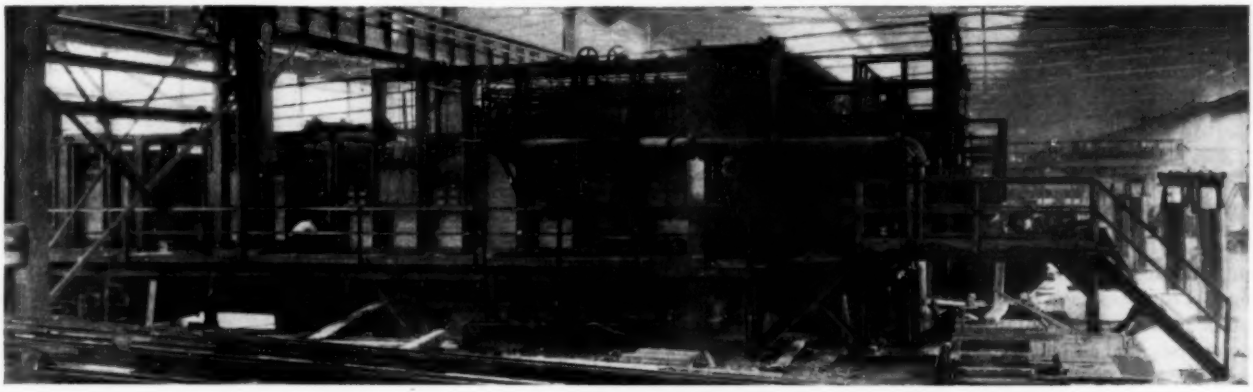

Fig. 5 Two Triple-Fired Furnaces at the Timken Roller Bearing Company Fired With Natural Gas

This may be spoken of, as the "quality of heating." The mill operator knows how important it is to have quality heating if the mill is continually to roll quality product with low delay periods and maintenance cost. To the steel plant executive it also means much. Low maintenance means lower production costs. Quality product finds a ready market.

Fundamentally, the way to obtain uniform heat distribution is the same in all furnaces; viz., first, that a uniform temperature be carried in the furnace at the discharge end, which temperature should be but slightly above that of the product to be discharged; second, this temperature condition should be maintained over a sufficient length of hearth to provide sufficient time for the material which is passing over the hearth to become thoroughly soaked and equalize its temperature throughout.

In other words, it requires the proper temperature and the proper time.

In the usual form of continuous furnace which has been used in the steel plants for many years, the furnace is fired above the steel at the discharge end. It may have underfiring or not, in accordance with the size of material to be heated, but the most of the fuel is fired at the discharge end immediately above the material waiting to be discharged. This is true in split flame-fired furnaces, the solid-hearth type of furnaces, and box-roof furnaces, in both end-discharged and side-discharged types. The main requirement of uniform heating necessarily imposes on all these furnaces the condition that the temperature carried be not much above that wanted in the steel at the point of discharge.

Many furnaces have been built which cannot fulfil this requirement, and as a result the material is melted, washed, ununiformly heated, and hearth maintenance is made excessive.

This temperature condition may be obtained more or less satisfactorily in end-fired furnaces as follows: (*a*) By using cold air for combustion, (*b*) by imperfect mixing of fuel and preheated air, causing delayed combustion, and (*c*) by the use of moderately heated air and semi-mixing. This is in effect a combination of (*a*) and (*b*). A fourth method and a positive one which has been developed in the last few years, is: (*d*) By constructing the soaking-hearth portion of the furnace as a separately fired independent unit and supplying only sufficient fuel to this chamber to compensate for the radiation losses of the chamber itself.

As already mentioned, it is exceedingly important that billets heated for piercing-mill use be heated uniformly throughout for

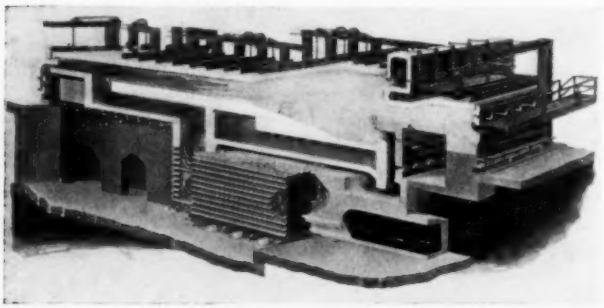

FIG. 6 ANOTHER FURNACE AT THE TIMKEN ROLLER BEARING COMPANY

proper piercing. It is worthy of note that for many years piercing-mill furnaces have been constructed in the main without the use of preheated air. Many companies would not consider the use of preheated air on this type furnace and, until recently, have been exceeding cautious even with regard to the kind of fuel they used. The reasons, although not always expressed are obvious. With end-fired furnaces, preheated air raises the temperature at the discharging point above that desirable in the steel, excepting with the lower B.t.u.-value fuels. Even with cold air some of the more rapid burning high B.t.u. fuels will give an excessive flame temperature unless carefully watched. The operators realized that the conditions were wrong for proper heating when using high B.t.u. fuels and preheated air, particularly if high flame temperatures, which are available, were permitted to develop. End-fired furnaces used for other types of mills frequently permit a greater range of temperature differential to be present in the discharged product, than is possible with piercing mills. It was for this reason that frequently recuperators and air heaters were indiscriminately applied to continuous furnaces which, in some cases, gave satisfactory operation while in others caused failures until revisions were made in the method of firing, which as shown in (*a*), (*b*), and (*c*) preceding, overcame the objections of hot air for combustion in the end-fired furnaces and minimized its excessive flame temperature.

It was learned rather quickly that highly preheated air caused overheating at the discharge end of the furnace. Many recuperator manufacturers then argued that 500 deg. to 600 deg. air was as high as was permissible and built the recuperator accordingly. Many people were against recuperators of any kind due to the failure they may have had from too high a temperature, excessive hearth maintenance, and poorly heated steel.

In looking once more at the methods listed for obtaining a satisfactory temperature surrounding the steel at the discharge point of the furnace, it is felt that the various means should be expanded somewhat. (*a*) Use of cold air for combustion results in high fuel cost, since the entire furnace temperature is low and no heat salvage is employed; (*b*) results in difficult control of the hot spot or point of thorough mixing, wherever it may be; fluctuating temperature conditions, high fuel consumption due to unburned fuel passing through the furnace in stratified layers, heavy scale losses due to free air, and low average temperature throughout the furnace which lessens the output; (*c*) gives more control and better efficiency than (*b*) but reduces the output and is uneconomical due to low preheat in the air. Each of the preceding methods are being used and are giving fairly good results, but to combustion engineers, high furnace efficiency and good quality of heating should go side by side, and the furnace which is obtaining one at the expense of the other is not a properly designed furnace.

Under the method explained in (*d*) in which the soaking hearth is a separately fired independent furnace unit, it is possible to obtain quality heating and at the same time use as highly preheated air for combustion as can be obtained, thus making the furnace an extremely efficient one as well as having one which is delivering properly heated steel.

Before going further into the desirable features of a continuous furnace, it is felt that it would be instructive to point out the analogy between the heating operation of a continuous furnace

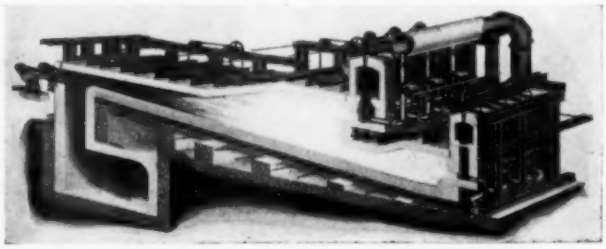

FIG. 7 DOUBLE-FIRED FURNACE AT THE WEST LEECHBURG STEEL COMPANY FIRED WITH PRODUCER GAS

and that occurring in the soaking pit. At first soaking pits were used, as their name implies, to perform only the operation of soaking. The hot ingot was charged while still containing molten metal and sufficient heat present to equalize the ingot at a temperature satisfactory for rolling. No additional fuel was supplied and a true soak was obtained. As production increased, the ingots arrived at the soaking pits too long after pouring to contain the required amount of heat and many times they were charged cold. The form of the soaking pit gradually changed until it was made a heating furnace as well as a soaking pit. Fuel-saving features were added, such as regenerators and recuperators. Still, the soaking operation was exactly the same as that in the original soaking pit; it still was a necessary part of the heating cycle; i.e., the soaking period is essential in order that the temperature of the entire mass may be equalized throughout before it is rolled. Modern pits first have a period of heating and end up as originally, with a period for soaking. During the heating period while the ingots are cold, it is desirable to apply a maximum flame temperature, and a high fuel rate is used in order to obtain rapid heating and, accordingly, higher production. In this period of the cycle, a high B.t.u. fuel and highly preheated air are desirable. As the ingots approach rolling temperature, a high flame temperature is not so desirable. The heater then may do one of several things. He may shut his pit entirely down and obtain preliminary soaking to equalize the ingots and prevent overheating, or he may reduce his firing rate greatly, or reduce the flame temperature of the combustible mixture for the same reason. Common practice calls for the heater to use an excess of gas. This not only lowers the flame temperature but provides a reduc-

ing atmosphere and reduces the oxidation losses. Such a practice is wasteful of fuel but is essential unless other means are provided to obtain the same results. If a pit had two fuels available, such as natural gas and blast-furnace gas, such a combination would permit obtaining ideal heating conditions. The natural gas, with highly preheated air, would give a maximum temperature during the heating portion of the cycle. When the ingots approached a finishing condition if the natural gas could be turned off and blast-furnace gas turned on, a wonderful finishing condition would be found in the soaking pit and maximum production and minimum time of heating would be required. The important points in the analogy of soaking-pit heating and continuous-furnace heating are that a rapid heating rate may be used until the steel approaches rolling temperature; from that point on the heating condition should be carried out in an atmosphere which is protective to the steel and still has a temperature which is but slightly above that required for rolling. The soaking-pit operator has to obtain these varying conditions throughout the heating cycle in a single chamber by the manipulation of his valves and dampers. These same conditions may be obtained in a continuous furnace by having the material pass through the furnace at a speed which will pass it through the various portions of the furnace so that it will be kept the proper amount of time in each section, with time allowed for a suitable period of equalization.

Any end-fired furnace should have its maximum temperature but slightly above that desired in the steel if it is to have a soaking condition at all, and a period of soaking is considered as important for quality heating in continuous furnace operation as it is necessary for soaking-pit use.

The analogy between pit-furnace operation and that desired in continuous-furnace quality heating is responsible for the actual design and construction of the Rust Zone-Controlled Double and Triple Fired furnaces. These furnaces are all provided with a soaking chamber and refractory hearth where uniform heat distribution throughout the mass of the product being heated, may be obtained at any predetermined temperature. This soaking chamber is supplied with only sufficient fuel to provide for the radiation losses from the chamber itself. No heating is attempted nor desired. Approximately 15 per cent of the total fuel is introduced into this chamber and this chamber is responsible only for the equalizing of the heat throughout the material passing through it before discharging, and is maintained at a temperature which is that desired in the product to be rolled. The fuel rate being only that required for supplying radiation losses, is a constant one. The remainder of the fuel, or 85 per cent of the total, is introduced into the heating chamber, either partially above and below the steel to be heated, or in the case of the double-fired furnace, all of it above. The fuel rate in the heating chamber is not a constant one. Since the heating chamber is responsible only for transferring heat to the steel at the rate desired by the mill, it fluctuates up and down in accordance with the mill requirements.

Flexibility

"Flexibility" listed as the second requirement for a good continuous furnace is obtained by varying the fuel rate of the heating-chamber burners. It is evident that this firing rate will, therefore, fluctuate with the mill and, in fact, keep step with it.

When considering end-fired furnaces from a flexibility standpoint, if they are designed correctly for a given tonnage, the firing ports will be correct for the firing rate desirable for the predetermined tonnage output. The flame characteristics will likewise be predetermined for a definite fuel rate and tonnage. Any changes from this fuel rate will result in a change in the flame characteristics and the resultant heating conditions in the furnace which are undesirable. Pushing an end-fired furnace beyond its rated capacity requires an increase in the average temperature throughout its length that heat may be transmitted to the steel more rapidly. Higher tonnage and increased furnace temperature requires increased firing rate. With the same rate of mixing, more heat will be liberated at the discharge point of the furnace than previously. This results in an increased temperature where it is undesirable. Overheating frequently occurs with its resultant cindering, slagging, and increased maintenance for the hearth and refractories as a result. At lowered tonnages than that for which the furnace is designed, a decreased fuel rate again changes conditions which are objectionable in the discharged material. In all cases, the slightest ununiformity in firing or improper adjustment of burners is immediately reflected in the discharged steel, since the burners at the discharge end have a double duty to perform: first, the heating of the material in the charging end of the furnace and, second, the proper conditioning of the material about to be discharged at the opposite end of the furnace. These two operations are completely isolated in the Rust zone-controlled continuous furnace; each being independent makes it possible to have a much more flexible furnace.

Low Oxidation Losses

The third requirement for a continuous furnace is listed as low oxidation losses. It is to be noted that the first two requirements have to do with actual furnace operation with reference to the mill. The third, low oxidation losses, takes its place in importance due to the actual amount of money that may be saved by a furnace having this requirement. This item is one too often overlooked and proper consideration has not been given it excepting in special cases where oxidation affects the resultant product as to quality. Oxidation is undesirable not only from a decarbonization standpoint, but, in addition, due to the large amount of money lost in scaling which occurs in the furnace that could be reduced on all kinds of steel. It is not uncommon for a mill to roll 50 tons per hour. On the basis of 20 hr. per day and 300 days per year, this amounts to 300,000 tons yearly. A scale loss of 1 per cent means 3000 tons which, at $40 per ton, amounts to $120,000 yearly loss. Many furnaces have a scale loss of from 2 per cent to 4 per cent. A furnace properly designed should not have oxidation losses of more than 1 per cent to 1½ per cent.

Oxidation in the furnace is dependent upon two things: first, reaction of iron with the oxidizing atmosphere whether it be free oxygen due to excess air, or its reaction with water vapor formed in the combustion of hydrogen containing fuels. The second important part of oxidation is the time the steel takes in passing through the furnace. It is well known that oxidation is a function of the time material is exposed to an oxidizing atmosphere, and since water vapor is always present in the furnace atmosphere using hydrogen containing fuels, this is an important cause of scale losses.

The zone-controlled double- and triple-fired furnaces make possible a minimum of oxidation losses. While the steel is passing through the soaking chamber, it is contained in a reducing atmosphere. The rate of heating in passing through the heating chamber is exceedingly high, and, therefore, the time the material is hot is kept to a minimum all of which tends to reduce oxidation. During mill delays there is no necessity of protecting the steel at the discharge point from overheating, since the temperature carried in the soaking chamber is approximately the rolling temperature desired. It is, therefore, unnecessary for the heater to check the air and lengthen the flame to protect this steel. It is only necessary to reduce the firing rate in the heating chamber. In this manner, cold steel at the charging end of the furnace is maintained in its original condition and is not heated up during mill delays. This also reduces scaling.

Low Furnace Maintenance

Any furnace which has high flame temperatures where the temperature cannot be dissipated toward doing useful work will have high maintenance on the refractories. This is found in the end-fired furnace when excessive temperatures are used at the discharge point. The steel is hottest just before being discharged and its absorbing power is least. This puts the load on the furnace refractories which become overheated and cannot give up the heat by radiation to the steel rapidly enough to afford its own protection. The zone-controlled furnace has its highest temperatures developed in the heating chamber which is of sufficient size to permit the heat to radiate rapidly to the cold steel entering from the charging end. The highest temperatures are not where the steel is hottest, but are where the steel is relatively cold, and the ability of the steel to absorb heat rapidly due to the high differential of temperatures protects the refractories and reduces furnace maintenance.

The elimination of cindering, washing, and melting of steel in a continuous furnace reduces furnace maintenance to a minimum, particularly with regard to the soaking hearth where the temperature prevents cindering and the chrome-ore facing is provided to withstand the abrasion of the material passing over it.

Low Fuel Consumption

The fifth requirement for proper continuous furnace design calls for low fuel consumption. End-fired furnaces cannot use highly preheated air and gain the benefit of the high flame temperature which is possible of development. The zone-controlled furnace, on the other hand, welcomes the highest preheat that can be obtained and uses the preheated air in the heating chamber where the steel will rapidly absorb the heat given up from the resultant high-temperature flame with the corresponding beneficial effect on increased efficiency.

Since radiation is a function of the difference of the fourth powers of the absolute temperatures of the material being heated and the radiating body, a few simple calculations will effectively show the desirability of using the highest flame temperatures which can be obtained, with the subsequent benefit of reduced fuel consumption and increased efficiency.

Any continuous furnace will show a reduced fuel consumption per ton as the tonnage output increases. The zone-controlled furnace can be pushed beyond its rated capacity as far as 50 per cent. Since the heating operation is separate from the quality of heating contained in the discharged product, the heating-chamber firing rate may be speeded up with a corresponding increase in downtake temperatures which is required when the tonnage is increased. In spite of the increased downtake temperatures, the fuel consumption per ton is reduced due to the higher capacity output. This overload capacity feature is one entirely absent in the end-fired furnace, although some additional capacity is frequently obtained from this type furnace, the amount of which, however, is entirely dependent upon how poor a quality of heating the rolling operation will put up with. In actual operation the zone-controlled furnace of the same length as an end-fired furnace, will surpass the end-fired furnace at least 25 per cent in capacity and still give the same quality of heating as at normal rating. When it is considered that the heating is done in the zone-controlled furnace only in the heating chamber, it is readily seen that this high rate of heat transfer is an important one since the zone-controlled furnace is, in effect, from 10 ft. to 15 ft. shorter than the end-fired furnace, although the overall length of each may be the same.

Ease of Control

The sixth requirement of a properly designed continuous furnace calls for ease of control. It is felt that great progress has been made in the past few years with regard to control features on these furnaces. At the present time, it is possible to install automatic temperature control in order to maintain a constant temperature condition in the discharge end of the furnace. Gas and air proportioning controls can be satisfactorily employed. By a combination of the two working in conjunction with an automatic draft regulator, the heater's work is made quite easy. The zone-controlled furnace, to be completely equipped, should have an automatic temperature control in the soaking chamber, together with proportional control equipment. The draft regulator would maintain a constant pressure condition in the furnace. The heating-chamber burners should be equipped with proportional control. Thus the heater would have but one valve to regulate, that controlling the gas flow to the heating chamber burners. This he would operate in accordance with the mill demand.

A combination of heating and soaking chamber eliminates to a large extent the requirement for delicate adjustment of firing rates and fine adjustments of burner equipment which is extremely difficult with high-capacity burners. It does this by providing a period of time for the steel to obtain the proper heating conditions after it leaves the heating chamber while passing over the soaking hearth.

An important feature of the zone-controlled furnace is the restriction which is provided by the suspended-roof construction between the heating and soaking chambers. This restriction accomplishes two beneficial results. In the first place, it effectively prevents heat from being radiated into the soaking chamber from the high-temperature heating chamber, by effectively shielding the material on the hearth. Without this restriction, the soaking operation could not be fully accomplished. The second beneficial result is obtained by throttling the flow of waste gases from the soaking chamber. In so doing, a positive pressure is maintained in the soaking chamber which prevents the infiltration of air up the discharge slope. Not only does the restriction prevent infiltration, but it likewise causes the soaking chamber to become independent of the pressure conditions carried in the heating chamber at different rates of firing. The height of the restricted roof portion is calculated to be that correct for the fuel rate of the soaking chamber which, by its constancy, makes unnecessary any further control.

Preheated Air

With the quantity and quality of the heating operation separated, it will be readily seen that the heat-salvage device, whether tile recuperator, alloy recuperator, or regenerative preheater, should be considered on its merits alone and from the return given by the added investment. The zone-controlled furnace places no limitations upon the degree of preheat in the air. For this reason, any heat-salvage device may be considered as operating at its greatest possible efficiency and its corresponding return can be fairly calculated.

Rust zone-controlled furnaces are operating with Rust refractory-tile recuperators, Mantle recuperators, and Blaw-Knox regenerative air preheaters, furnishing preheated air for combustion. Others are installed with cold air where conditions warrant it. In many cases, any one of the above heat-salvage devices may be used satisfactorily. The one exception which should be mentioned here consists of high combustion-chamber furnaces which require the use of producer gas as fuel. Since producer gas has but 1 in. or so of pressure available, it is found desirable to use some form of air heater other than the tile recuperator in order to deliver the hot air under an appreciable pressure. It is always desirable that either the fuel or the air be under sufficient pressure to provide proper mixing through a burner block and at the same time provide proper flame directional

characteristics. With the refractory-tile recuperator, the pressure of the air delivered to the top heating burners may be as high as 0.3 in. of water. This is not sufficient with producer gas as fuel due to the static pressure found in the high heating chamber.

A number of end-fired furnaces having high-combustion chambers, have been constructed with refractory-tile recuperators and producer gas for fuel. Auxiliary cold-air pressure jets are employed to furnish the medium by which preheated air and low-pressure gas are forced into the furnace chamber. Cold-air jets have a double objection. Cold air reduces the temperature of the preheated air for combustion which it is helping into the furnace and, accordingly, reduces the efficiency of the heat salvage apparatus and the furnace as a whole. At the same time, it necessitates the use of mechanical equipment to furnish the second source of air supply and complicates the heater's work by having additional valves and regulation dampers to handle. The reduced air temperature of the mixture of hot and cold air lowers the flame temperature of the furnace. In one way of speaking, this is a desirable feature for end-fired furnaces, as a lowered flame temperature would more nearly approximate the temperature of the steel at the discharging point. However, the benefit of the heat-salvage device is reduced, and in many cases would not be a paying proposition when operating under these conditions, and is, accordingly, contrary to proper combustion-engineering principles.

On any type of continuous furnace having a high-combustion chamber, any type of air-heating equipment may be used satisfactorily by using any fuel other than producer gas. The type of heat-salvage device to be used depends entirely upon existing plant conditions and the entire mill layout.

Summary

The author has attempted:

1 To prepare a chart containing a classification of rolling-mill furnaces which may assist the steel-plant operator in the determination of the correct type of furnace for his specific requirements, and at the same time divide furnaces into classes which make possible a fair means of comparison with regard to fuel consumption, operating efficiency and tonnage output.

2 To point out that the main requirement for all types of continuous furnaces is to maintain a temperature at the point of discharge approximately the same as that desired in the discharged material, that quality heating may be obtained.

3 To point out that if quality heating is obtained from an end-fired furnace where the maximum temperature is carried at the discharging point, many undesirable conditions must be put up with, such as slow heating, a long furnace, high oxidation losses, and the elimination of the full benefits possible with preheated air.

4 To explain that if only sufficient fuel is introduced at the discharge point to care for radiation losses and the remainder is fired in a separate heating chamber, it is possible separately to control the quantity of heating from the quality of heating. This condition makes possible a rapid-heating furnace, one flexible of control and capacity output, reduced radiation losses, and the use of air-preheating equipment at the greatest efficiency.

Discussion

E. A. Hawk.[2] The author has brought out many interesting points in regard to continuous reheating furnaces. In this day of higher efficiencies and greater economies, complete and thorough studies of the different heating problems are necessary.

[2] Fuel Engineer, Department of Research and Technology, Tennessee Coal, Iron & R. R. Co., Ensley, Ala.

Recent installations of triple-fired continuous furnaces with soaking hearths in the Birmingham district include:

(1) Two 15-ton high-pressure natural-gas-fired furnaces, without recuperators, heating 4-in. by 4-in. billets.

(2) One 30-ton low-pressure by-product gas-fired furnace, with tile recuperators, heating structural shapes including 5-in. by 5-in. blooms up to 18-in. beam blanks, the soaking hearth being fired with high-pressure by-product gas under automatic temperature control.

The performance of these furnaces in regard to tonnage and product heated is satisfactory.

In order to show the difference in the rate of heat absorption by steel in passing through a continuous furnace, the chart

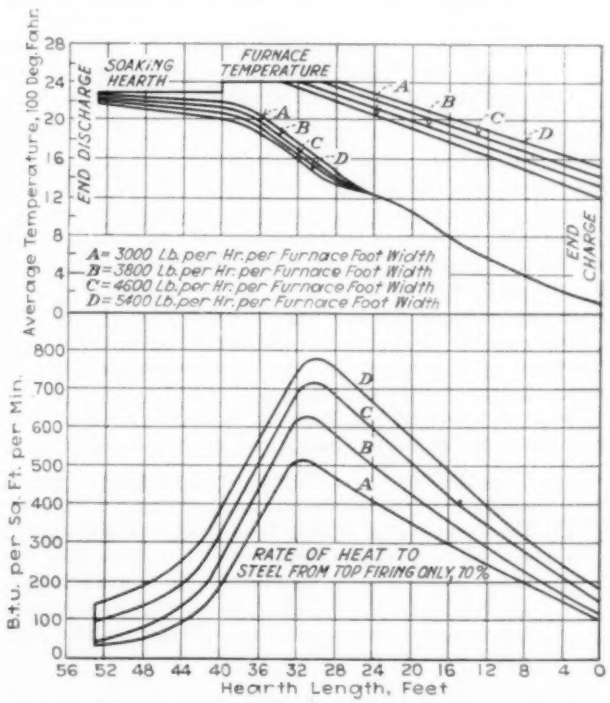

Fig. 8 Continuous Furnace, Triple Fired, Heating 8-In. by 8-In. Blooms

(Fig. 8) is shown. Consider a triple-fired furnace having a soaking zone and top and bottom firing in the main body of the furnace, heating 8-in. by 8-in. blooms at the following rates:

A = 3000 lb. per hr. per furnace foot width = 56.6 lb. per sq. ft. per hr.
B = 3800 lb. per hr. per furnace foot width = 71.7 lb. per sq. ft. per hr.
C = 4600 lb. per hr. per furnace foot width = 86.7 lb. per sq. ft. per hr.
D = 5400 lb. per hr. per furnace foot width = 101.8 lb. per sq. ft. per hr.

As the tonnage rate increases, it is necessary to extend the high-flame temperature zone in the direction of charging, resulting in a slight increase in waste-gas temperature. After passing through the 1150 to 1400 deg. fahr. critical range, the rate of temperature increase becomes greater, and overheating results unless the furnace temperature is closely regulated. By maintaining the soaking zone at constant temperature and varying the fuel rate in the main body of the furnace according to the demand, this type of furnace serves the same purpose as a flywheel on a rolling mill, storing up energy during light loads, to be relieved again during periods of peak loads.

When this type of continuous furnace is used in conjunction with in-and-out furnaces supplying steel to a mill where the maximum rolling rate is 100 tons per hour and where one in-and-out furnace can discharge 50 tons in half an hour, the continuous

furnace must discharge at a similar rate; for example, 25 tons during a 15-min. period of each hour. This high rate of discharge is made possible by use of the soaking zone designed to hold sufficient tonnage at rolling temperature.

When heating 2-in. by 2-in. billets, the advantages of the two-zone furnace are not as apparent, as:

(1) The temperature difference between surface and center of the billet is small
(2) Heating through the 1150 to 1400 deg. fahr. range is not so pronounced
(3) As bottom firing is not required, there would be no skid marks to remove with a soaking hearth
(4) With side discharge, the furnaces are less subject to cold-air infiltration, except when too steep a sloping hearth is used
(5) Extending the high-temperature zone too far back will cause 2-in. by 2-in. billets in a sloping hearth to slip past the discharge door if the slope is greater than 2 in. per foot.

Even for the large-size billets, such as 3 in. by 3 in. and 4 in. by 4 in., the advantages of the two-zone furnace may not be so apparent, especially when the rate of heating is fairly uniform. For example, a merchant mill furnace in the Birmingham district has given satisfactory results heating 4-in. by 4-in. billets, 20 ft. long, this furnace being top-fired only, having level hearth and dry skids and using proportioned by-product gas and cold air.

The use of preheated air is not necessarily limited to the two-zone furnace. Higher preheats are being used successfully by proper regulation of the rate of mixing air and fuel.

The writer considers the two-zone furnace as primarily intended for large sections requiring end discharge, as:

(1) Large sections require top and bottom firing and skid marks are removed in the soaking zone
(2) The soaking zone is made long enough to provide the mill for high rates of rolling
(3) Large sections must preferably be end-discharged; air infiltration is reduced considerably by employing a soaking hearth operated under a slight positive pressure.

Too liberal size of water-cooled skid pipes and skid supports increases water-cooling losses very rapidly. Cooling-water losses may amount to as high as 25 per cent of the total fuel supply.

For some operations, the in-and-out type of furnace may be preferred to the continuous furnace, as:

(1) When charging hot steel
(2) Slabs or flats requiring a wash heat to remove scale
(3) To eliminate buckling which may occur with light slabs or flats in a continuous furnace
(4) On mills rolling high- and low-carbon steels
(5) Miscellaneous small tonnages.

Quality of product, of course, is essential. The type of fuel available, mill conditions, and labor costs make each heating problem an individual study. The advent of automatic control of temperature, of air and fuel ratios, and of furnace draft is receiving considerable attention, not only in the application to new furnaces, but to existing furnaces as well.

G. T. Hollett.[3] The subject of furnace design, with actual authentic data thereon, is noticeable on account of its absence. Until very recently the subject of furnace design received little scientific study in this country. Fuel costs were only a small part of the total cost of the manufacture, and the quality of product was not so exacting, so that most reheating furnaces were designed and constructed by the mason foreman or other local talent. A great deal of credit must be given to those practical men who perhaps could not actually calculate what the areas should be or what size of port to use, but through trial could observe results, and at each rebuilding of the furnace would approach their ideals. This school of practice is one quite often necessary even at the present time, as usually minor changes are necessary on a supposedly fine, technically constructed furnace, due to the designer not securing all the facts or because of some alibi not recorded in the contract and hence being at the purchaser's expense.

The author has given a classification of furnaces which enables us to divide the furnaces into groups. These divisions are arbitrary, and while no definite line separates a wide furnace from a medium furnace or a narrow furnace, this classification does give a division point. We may not all agree on the exact dimensions, but our arguments for division points may not be any more weighty than the author's. It is unfortunate that all wide furnaces cannot be constructed with side discharge. With proper forethought this can be accomplished in most cases and represents a neat return on fuel costs. A side discharge is impractical, and end discharge must be used as is necessary when handling heavy sections. A proper door-opening mechanism should be provided so as to keep the end of the furnace closed except when the steel is being discharged. This has been worked out in several cases and has proved practicable.

The author has emphasized uniform heating, particularly for piercing furnaces. This is becoming more and more true of other products as well. The open-hearth or bessemer may make a good quality of steel only to have it ruined by improper heating in the reheating furnaces. With the quality of product the trade is now demanding, it is not permissible to subject the steel to tremendous heat shocks and then expect to produce a steel that will not show structural fractures. If we can deliver steel to the mills after it has been heated up by a proper cycle from end to end and center to outside, the chipping expense and rejections would be less than the average practice. Proper furnace design will help to accomplish this result. Quality heating requires a definite cycle, and this cycle should not be exceeded even in a zone-controlled furnace. If a furnace is properly rated, then the capacity cannot be increased 50 per cent without definitely decreasing the quality of heating, regardless of type of furnace. As soon as a zone-controlled furnace is pushed above the point where the steel is entering the soaking zone below the proper temperature, the purpose of the soaking zone is defeated and it becomes an end-fired furnace.

The six continuous furnace-operating requirements are well taken. Uniform heat distribution throughout the mass of discharged product at a predetermined temperature is what operators are striving for. Flexibility as to tonnage output without any appreciable loss in efficiency or change in quality of heating may be obtained if the output of the mill does not vary over too wide a range. Where this variation is over a wider range, the radiation and fixed losses are such a large percentage of the total input at the low ratings that this will not be true. Fortunately most of the continuous-heating furnaces are operating on mills that have a fairly steady rate of reheating. The low oxidation loss is a very much desired item and good results are being obtained. However, after observation of various zone-controlled furnaces, we are making provisions to remove scale from below the hot portion of the heating zone on the three continuous-heating furnaces we are installing. The low furnace maintenance is very desirable. We often sacrifice this point and install a

[3] Illinois Steel Company, South Chicago, Ill.

furnace for, say, 25 tons per hour and then expect the operator to produce 30 to 35 tons without increasing the maintenance cost. The rating of the furnace cannot be increased materially if the original rating of the furnace was properly calculated unless one defeats the zone principle and makes the soaking zone a part of the heating chamber. One should not try to operate a furnace at 50 per cent over its true rating and expect results. The writer has found this to be true in some furnaces of this type recently inspected. With a fixed height of throat between the soaking chamber and the heating chamber it is impossible to adequately throttle the flow of gases from the soaking chamber to the heating chamber unless the furnace is operated on one definite thickness of material heated. In some instances the variation in thickness of steel being heated may affect the area of the throat as much as 25 to 30 per cent, which will materially change the draft condition in the soaking chamber. This perhaps is the exception to the rule, but it is something that the writer is facing in actual practice.

Author's Closure

The author appreciates the frank discussion, which has brought out many interesting points.

It is particularly evident that all think alike with regard to the importance of "quality heating," the first requisite of a well-designed continuous furnace.

Mr. Hawk apparently believes that zone-fired furnaces are mainly advantageous for use with heavy sections. This is incorrect, as will be quickly seen if one thinks of the prime requisite of a properly designed continuous furnace—namely, "quality heating" or uniformity of heat distribution.

The design of the zone-fired furnace calls for a soaking chamber which has the sole duty of discharging steel uniformly heated throughout and at the desired temperature. This can be obtained only if the temperature at the discharge point of the furnace is maintained at or slightly above the predetermined temperature desired.

This is self-evident in the case of furnaces heating thin, wide slabs. Zone-fired furnaces at the plant of the Republic Steel Corporation, Youngstown, Ohio, are heating slabs $2^3/_4$ in. thick up to 35 in. in width and 12 ft. long. The soaking chamber proves its worth in delivering these slabs so uniform in temperature from front to back that a maximum of a few thousandths variation is found in the finished plate from end to end and from side to side.

Should an end-fired furnace use delayed combustion or regulated rate of mixing to prevent excessive temperatures when using preheated air, it is possible that for one definite tonnage rate correct temperature conditions in the discharged product might be realized. However, it would be impossible to maintain these conditions for fluctuating rates of output, and it also would be impossible to have a higher temperature in the furnace than that carried at the discharge end. This would result in a lowered efficiency, which condition is overcome by the use of zone firing, since the heating chamber employs as high a temperature as can be realized, with the amount of heat liberated or fuel fired varying with the tonnage rate desired.

The author has in mind a second installation which is used to heat billets and flats from 2 to 4 in. in thickness and 15 ft. in length. This is a double-fired furnace having no underfiring nor watercooling. It is located at the plant of the Steel Company of Canada. Due to the varying nature of orders oftentimes the tonnage demands vary from 10 tons per hour to 35 tons per hour, although the furnace is normally rated at 25 tons per hour.

Obviously when heating at the low rates it would be foolish to use the soaking chamber as anything but a soaking chamber. In this case the heating-chamber burners are turned almost entirely out; in fact, for the first week of operation they were not used at all. This resulted in the soaking chamber being carried only at a soaking temperature, with the entering portion of it employed for heating. The time of travel through the soaking chamber is regulated by the tonnage demand. This permits the same length of time in the soaking heat as would be obtained at the higher tonnages; however, the distance of travel is much less. In other words, if a soaking hearth 12 ft. long is required to give the proper time of soaking at 30 tons per hour, then a soaking hearth 2 ft. long would give the same time for soaking when operating at 5 tons per hour.

During low-tonnage operation practically 85 per cent of the fuel is shut off by cutting out the heating-chamber burners.

The author agrees with Mr. Hawk that flexibility as to tonnage output without any appreciable drop in efficiency is impossible over extra-wide ranges of tonnage. However, he wishes to point out that since the soaking chamber utilizes only approximately 15 per cent of the total fuel when operating at the normal rating of the furnace, a zone-fired furnace makes possible a much greater flexibility and a wider range of tonnage, since it is possible to vary the 85 per cent downward to zero and still for overload capacities increase it to change the proportions to approximately 90 to 10.

The author believes that a proper normal tonnage rating for a furnace should take into consideration furnace maintenance. Every one knows that furnace maintenance goes up with excessive overloads. If the furnace is properly rated at 20 tons per hour, such as the installation at Republic Steel Corporation, it should be able to be pushed without excessive maintenance increase to 25 tons per hour. If desired, it also should be able to be pushed beyond this, with the operator well knowing that increased maintenance will result. Tonnages of 31 tons per hour have been obtained over an appreciable length of time without excessive maintenance having yet been noticed. However, undoubtedly such overloads will shorten the life of any furnace.

The Steel Company of Canada double-fired furnace with a 25-ton normal rating has delivered from 5 to 38 tons per hour.

The Timken Roller Bearing triple-fired installation with a normal rating of 40 tons per hour operates nicely at 50 tons per hour and has turned out $61^1/_2$ tons per hour at various times.

It is to be borne in mind that a zone-fired furnace obtains its higher tonnage and greater overload capacity, not by using the soaking chamber as a heating chamber (except when extra thin stock is being heated, which of course requires a shorter time for soaking), but by increasing the high-temperature portion of the furnace and permitting the steel to more rapidly enter the high-temperature zone and thus heat more rapidly in the heating chamber. It is also to be remembered that at higher tonnages an increase in temperature of the waste gases increases the temperature of the preheated air, which in turn increases the heating-chamber flame temperature. This is more evident in the zone-fired furnace using cold air for combustion on the soaking chamber than on the ordinary end-fired furnace, since only approximately 85 per cent of the air for combustion is preheated, yet 100 per cent of the waste gases is available for this heating.

With regard to the observations on scale losses in Mr. Hollett's discussion, the author wishes to point out that overheating may occur with regard to time as well as temperature.

Every one knows that a piece of steel which is hot too long, as occurs during delay periods, has more scale on it than when it is heated speedily as in normal operation of the furnace.

The tendency of a heater is to insure himself of plenty of hot steel. A zone-fired type of furnace makes it possible for him to play extra-safe in his heating. This sometimes results in

heating the steel too far back in the heating chamber, with the formation of more scale than is necessary. If the operator properly controls the heating-chamber burners so that the billets are permitted only their proper time for soaking, which is dependent entirely upon their thickness, both fuel and scale can be saved. It therefore behooves the users of zone-fired furnaces to have careful, intelligent heaters if the highest efficiency possible is to be obtained.

Furnace maintenance, particularly with regard to refractories, is noticeably high whenever more heat is liberated in any portion of the furnace than can be absorbed rapidly by the steel. This is noticed at the discharge point in ordinary end-fired furnaces where the steel and flame are hottest, the differential being so reduced as to permit the refractories to become overheated frequently.

It is interesting to note the temperature condition in a zone-fired furnace. It will be found that temperatures of the refractories in the downtakes are much higher than the temperatures of the roof in the channel as far as 30 ft. from the downtakes. This should explain the reason for high maintenance. The low roof temperatures are due to the ability of the steel to absorb heat more rapidly than the refractories, and hence the refractories radiate this heat rather than maintain it. It is for this reason that the heating chamber of the zone-fired furnace has shown such a low maintenance requirement.

The heating chamber is large and contains relatively cool steel as compared to the temperature condition found in the ordinary end-fired furnace at the discharge point, where in each case the highest temperatures are carried.

The cooled steel rapidly absorbs the heat and protects refractories in the one case, where this is not possible in the other due to the higher temperature of the steel.

German and American Steel-Plant Practice

By F. L. ESTEP,[1] NEW YORK, N. Y.

The United States leads the world in the production of steel and Germany has again become second. The greater percentage of the total amount of steel made in the United States is used domestically, whereas, on the other hand, a very large percentage made in Germany is exported. This in itself has had a certain influence upon the processes developed, methods pursued in the two countries, and the supply and cost of raw materials. Another factor which has affected the methods and the equipment used is the quantity and quality of labor available and the wages which must be paid.

In Germany today the greater percentage of ore used comes from foreign countries, while in the United States the great bulk of the ore is mined at home. Coal is plentiful and of good quality in Germany, but its price for metallurgical purposes is higher today than the coals commonly used in the United States for the same purpose. This paper shows to some extent where the processes differ.

Coke Plants

THERE is little to choose between the latest coke plants of the United States and Germany. Ovens have been designed and built of sizes to suit the particular coals. Both countries have gone to high ovens, and widths have been reduced in order to lower the coking time. In both countries the heating of the ovens is under automatic control; all mechanism for the control of temperature and the handling of gases and of by-products has been made accessible. Means have been provided for quenching and handling the coke at the ovens, and delivering either directly to the points of use or to central points for distribution or shipment.

It is quite common in Germany to find coke ovens built at the coal mines, so that coal delivered from the tipple passes through a preparation and washing plant directly to the ovens. In the United States it is the practice to build ovens at the point nearest to the use of either the coke or gas, and haul the coal to the ovens.

Blast Furnaces

In the United States a blast-furnace shell, supported by a mantel and columns, carries the entire weight of the top and superstructure, and encloses the brickwork. In Germany the furnace lining is usually built and held together by bands, and separate columns extend from the ground to the top of the furnace and carry all the weight above.

The United States leads in the number and percentage of large furnaces. There are perhaps six furnaces in the United States that have averaged over 1000 tons per day for at least one month and one furnace which averaged over 1000 tons per day for the year 1928.

The methods of filling the furnaces are again different. The practice in the United States is to use double skips under automatic hoisting control, and also to lower and close both large and small bells automatically. In Germany, the almost general practice is to fill the furnaces by means of large circular buckets, which, when set on the furnace top, automatically discharge their contents into the furnace.

With the bin systems in common use in the United States, the amount of labor required for filling the furnaces has been reduced to the absolute minimum, whereas with the system in use in Germany the labor is greater. Several of the larger furnaces in the United States are today being charged with one man per shift for eight hours.

Because of the fact that since the war Germany has had to obtain ore from many different countries abroad, much of the ore received contains a very high percentage of fines which must be sintered. The percentage of sinter used in the burden is much higher than in the United States. This has enabled them to increase their productions very materially, lower their coke consumption per ton of pig, and lessen the pressure required on the furnaces.

The United States has advanced farther than Germany in the preparation of raw materials, other than the question of sinter. Ore is being crushed and sized, as is also the limestone. The same holds in regard to the crushing of coke, and it has become common practice to crush and screen the coke so that furnace coke will not exceed $3^1/_2$ in. maximum or 1 in. minimum in size.

In Germany blowing of blast furnaces and converters is almost always done by gas engines, whereas in the United States comparatively few gas engines are used and none has been installed for several years in any steel plants. Blowing in the United States in the plants with the larger furnaces is done almost exclusively with turbo-blowers. These have been developed to a very high degree of reliability and with very great reserve power, enabling one blower to deliver sufficient air for the largest furnace under all operating conditions of fluctuations in pressure up to as high as 35 lb. maximum.

In Germany a number of gas-blowing engines deliver air into a common cold-blast main leading to the stoves and blast furnaces. From this common supply of air each furnace receives its air through a valve, the pressure being reduced to that required for each individual furnace. In other words, the pressure in the system as a whole must at all times be in excess of the highest pressure on any particular furnace. From the standpoint of operation, to the mind of American blast-furnace men and engineers, this system is entirely wrong. Blast furnaces have reached such sizes and volumes that the requirements for air have surpassed the blowing capacity of any one single gas-engine unit which has been built to date.

Because of the comparatively high price of coal, it has always been essential that a steel plant in Germany operate at the highest possible thermal efficiency. This has necessarily involved the use of gas engines for blowing and for the generation of power. If and when Germany uses individual blowing units on each furnace, and when they size the raw materials along the lines mentioned, then, in conjunction with the 20 per cent to 30 per cent of sintered ore in the burden, it is the opinion of many Americans that Germany may again take the lead in output per blast furnace.

The difference in the over-all thermal efficiency of blowing equipment for a steel plant, between an installation using gas engines with waste-heat boilers and a modern high-pressure boiler plant burning blast-furnace gas, is steadily decreasing. Al

[1] Chief Engineer, Perin & Marshall. Mem. A.S.M.E.

Presented at a meeting of the Metropolitan Section, November 12, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

though the efficiencies will never be the same, the difference is becoming so small that, all things considered, including interest, depreciation, and maintenance, turbo-blowers will always hold their present supremacy for blast-furnace operation in the United States, and may have first consideration in the near future in Germany.

Because of the necessity during the past years for the cleaning of blast-furnace gas to a degree suitable for gas-engine purposes, German steel plants have been in a position to try this very clean gas for many different purposes, such as heating of stoves, general reheating purposes, and the mixing of blast-furnace gas with coke-oven gas for metallurgical and reheating purposes. In this respect they are at the present time far ahead of the United States, where there are only two or three installations using a mixture of blast-furnace and coke-oven gases.

In Germany it is common practice to granulate blast-furnace slag for adjacent cement plants, where properly prepared granulated slag is used in quantities varying from 60 per cent to 85 per cent in the manufacture of cement. In the United States, on account of the comparatively low cost of quarrying, crushing, and preparing limestone, very little blast-furnace slag has been used in the manufacture of cement.

Steel-Making

In Germany about 45 per cent of the total amount of steel made is produced by the Thomas process. The remainder is made in open-hearth furnaces, usually of the stationary type, where practically all of the scrap made in a plant is melted. Thomas steel is used for ordinary products, such as rails, structurals, merchant material, rods, and wire. Open-hearth steel is used for seamless tubing, sheets, tinplate, and other products where the open-hearth grade is better suited.

In the United States the percentage of the total production of steel ingots by the bessemer process has steadily decreased over the last 30 years. Whereas in 1900, 6,684,700 tons, or 65.5 per cent of the total, was made by this process, in 1928 there was made 6,591,745 tons; but this was only 13.1 per cent of the whole.

Because of the predominance of Thomas steel in Germany, an arrangement of plant different from United States plants has been possible. Thomas steel can be poured and stripped very quickly, and for many products can be brought to a rolling temperature without fuel by merely enclosing in a single ingot pit for about two hours.

In practically all plants in Germany the slag made by the Thomas process is made into fertilizer containing approximately 15 per cent to 16 per cent of P_2O_5 soluble in citric acid. In one plant in the United States where the duplex process is used, the primary or first slag is poured off and made into fertilizer containing about 18 per cent P_2O_5.

The later open-hearth furnaces in the United States are larger than those in Germany. They range from 100 to 150 tons rated capacity, with a few furnaces of 250 and one of 400 tons, while in Germany the later furnaces range from 80 to 100 tons capacity, with a few up to 200 tons. In the United States practically all furnaces, except those originally designed for the duplex process, are of the stationary type. In Germany there are a few tilting furnaces.

The construction of stationary open-hearth furnaces in the two countries is generally the same, but there are some points where they differ more or less radically. In the United States furnaces are equipped with very efficient water-cooled doors, frames, and ports to insure the longest life and the minimum delay of production throughout the year. Water cooling is not done on German furnaces to any marked extent. American furnaces are also built with sloping back walls which very greatly increase the furnace life and minimize delays in production.

In Germany checkers have been developed to a much higher degree of efficiency in heat transfer than is common practice in the United States. They are building checkers of large volume and extreme height, making it possible to preheat the air and gas to a very high temperature. This means also that the temperature of the stack gases is very much less than here, so low in fact that it is an uncommon thing to find a waste-heat boiler installed on an open-hearth furnace in Germany. The claim is made that the proper place to secure the highest overall efficiency in open-hearth operation is in the heat transfer in the checkers, and not by the absorption of excess heat in waste-heat boilers. The latter are used to a very marked extent in the United States. Open-hearth design in the United States must therefore take this point into very serious consideration and develop checkers of proper dimensions, with checker openings suitable to secure maximum economy without waste-heat boilers.

Fuel consumption per ton of ingots in Germany is generally considerably better. This is partially due to the use of a mixture of blast-furnace and coke-oven gas in their open-hearth furnaces, this having been developed to a very high degree of efficiency and reliability. Their late furnaces are equipped with mixing and regulating devices and a full complement of instruments per furnace, whereby it is possible to know at all times the exact calorific value of the mixture, the percentage of CO and CO_2 in the waste gases, the stack temperature, and the general over-all efficiency of the furnace. Furthermore, they have become very skilled in the operation of a furnace with this fuel, using a rich mixture for initial melting, and during the latter portion of the melting time reducing the calorific value of the mixture by the addition of more blast-furnace gas, and thereby effecting an over-all economy of operation that is quite remarkable.

In the United States the percentage of scrap and hot metal used at the open hearth depends largely upon the price and quantity of scrap available. It usually fluctuates from 40 per cent scrap and 60 per cent hot metal to 55 per cent scrap and 45 per cent hot metal. It has been found that operations are slowed down materially if the percentage of hot metal is much over 60 per cent. In Germany the percentage of scrap is, as a rule, much higher, because if a plant has both the Thomas and open-hearth processes, practically all of the scrap is used in the open hearth, a small percentage occasionally being charged into the converters.

In the United States there are eight plants with equipment of mixers, converters, and furnaces for the manufacture of steel by the duplex process. One plant has always operated by this process and is running at full capacity, making about 70 per cent of rail steel and 30 per cent of soft steel. In the remaining plants the equipment is used in various ways. In one or two plants the furnaces are used as straight open hearth and the converters for straight bessemer; in others some bessemer steel is made and duplex furnaces are used by a modified process, and in others some of the furnaces are used as straight open hearth and the remainder run on a modified duplex process. However, in one plant where there are three duplex furnaces, one is used as a straight open hearth to melt practically all of the plant scrap, and the other two are operated by the (strictly speaking) duplex process and make high-quality steel, including high-carbon steel for seamless tubes.

The design of open-hearth furnaces in the United States has not yet reached the limit of proper proportions and design for long life, combined with greatest economy. As has been mentioned previously the design, size, and proportion of checkers, the size and laying of the checker brick, together with the use

of fuel in the form of a mixture of blast-furnace and coke-oven gas under automatic control, will undoubtedly greatly reduce the time required per heat for the manufacture of steel of any given quality.

Mills

The first rolling operation of finished steel products in Germany, as in the United States for the great majority, must necessarily be that of converting an ingot into a bloom or a slab for finishing into some specific product on another mill.

Soaking Pits

Because of the fact that in Germany a large percentage of ingots is made by the Thomas process where heats varying from 25 tons to 40 tons are usually blown, it is possible to strip the ingots very quickly after being poured, and get them very quickly into single-hole ingot pits, where they are allowed to soak. For the soft steel made by the Thomas process, the ingots reach a rolling temperature without application of heat. On rail steel and soft steel for some products, heat is applied usually in the form of blast-furnace gas to the soaking pits for a short length of time after the ingot is first soaked and has equalized its own temperature. In a plant making Thomas steel about 40 per cent to 60 per cent of the total number of pits are without gas.

In the United States, where the great percentage of steel is made by the open-hearth process, it becomes essential that the soaking pits and blooming mill be separated from the open-hearth plant with an intermediate stripping point. This means that it is impossible to put ingots into the soaking pits at as high a temperature as is possible in a plant making steel by the Thomas process.

The soaking pits therefore in the United States have been developed along different lines. Heating is done with producer gas, coke-oven gas, a mixture of coke-oven gas and producer gas, tar, a mixture of tar and coke-oven gas, and, infrequently, with oil. Practically all pits are provided with checkers for preheating both air and gas. However, in one or two plants where coke-oven gas is used, a pit has been developed without checkers, using the gas under automatically controlled pressure with a special type of burner. It is claimed that the fuel economy over a year in pits heated in this way is equal to or better than the general average in the United States of pits with checkers. Furthermore, it does not cost more than 40 per cent of that of the ordinary type and the maintenance is very much reduced.

In regard to fuel consumption, there has always been a great deal of confusion and misunderstanding between the results obtained in Germany and the United States. This is due to the fact that, usually, proper allowance is not made for the large percentage of steel made in Germany by the Thomas process and, furthermore, that perhaps 60 per cent of the total steel made by that process in any given plant requires no heat whatever. If they were put on a strictly comparative basis for open-hearth operation only, it will be found that the average fuel consumption per ton of ingot in Germany would be somewhat less than that in the United States, but no better than in some of the later and best-operated soaking pits in the latter country. These pits can be operated on about 100 lb. of coal equivalent per ton of ingots, or expressed in another manner, 4.5 per cent of fuel.

Blooming and Heavy Finishing Mills

Blooming mills in both countries are practically all of the two-high reversing type, the later and larger installations all being motor driven. In each country ingots, usually of 4 to 5.5 tons in weight, are rolled with the minimum number of passes practical into a bloom of a size suitable for transfer to a finishing mill.

The finishing of rails, heavy and medium structural shapes, and some special shapes, is done in Germany almost generally upon two-high reversing mills, consisting of two or three stands adjacent to and usually in line with the blooming mill. Finishing is done from the original ingot heat. The blooming and finishing mills for this class of product in Germany are somewhat larger than those in common use in the United States. Blooming mills will run up to 52 in. pitch diameter of pinions, whereas in the United States the corresponding type of blooming mills range from 40 to 45 in. pinion diameter. German finishing mills, such as those referred to, have rolls of from 800 to 900 mm. in diameter, whereas for the finishing of the same sized structurals in the United States the mills do not exceed 32 in. in diameter.

In the United States a mill to roll rails or structurals up to 24-in. beams is arranged differently than in Germany. Here it is customary to bloom an ingot, deliver it on the back side of the mill, crop it, and send it in blooms of proper lengths to the finishing mill. In some few installations a two-high engine- or motor-driven reversing rougher is interposed between the blooming and finishing mills. In many plants in the United States, sections corresponding to those which would be rolled in Germany direct from the ingot heat are reheated before rolling.

From the viewpoint of American engineers and mill operators, the layout of the German soaking pits, blooming mill, and heavy finishing mills in relation to each other is awkward and wrong. This is not merely a question of difference of opinion. It is practically a certainty that, for the majority of products which can be rolled direct from the original ingot heat, if mills of the two types were installed side by side and given the same materials to roll into the same finished products, the American mill would produce a greater tonnage in a given length of time with less labor. The first cost of the American installation would be little if any higher.

Plate Mills

In the United States practically all plate mills are of the three-high of "Lauth" type, with large-diameter top and bottom rolls and a smaller-diameter middle roll. There is one installation of a very heavy four-high engine-driven, reversing plate mill, the top and bottom backing-up rolls being large in diameter and the two working rolls small. In some plants two stands of three-high rolls make a complete mill unit, one stand being used for roughing to width and rolling to a medium thickness, while the finishing is done on the second stand, thus giving a better quality of surface to the plate.

There are also several two-high, reversing universal mills, and one or two three-high mills. These roll universal plates up to a maximum width of approximately 48 in., and by removal of the vertical rolls can roll sheared plate to a width approximating 50 per cent wider than the maximum universal width. These mills are largely used for skelp for medium diameter of lap-weld pipe.

Merchant Mills

There is a great difference between the types and capacities of mills in the two countries for the rolling of what is termed "merchant products." These include rounds and squares from $^3/_8$ in. minimum to 3 in. maximum; angles, tees, and other shapes from 1 in. by 1 in. minimum to 4 in. by 4 in. maximum; and the corresponding range of rectangles, flats, and special shapes.

Until very recently, practically all the mills in Germany rolling this class of product have been of a type producing a

very limited tonnage per month with a large number of men required for their operation. There were very few mechanical devices to save labor or increase the tonnage, and insufficient facilities for the finishing and handling of large productions.

In the United States there has been a gradual development for many years of special mills to roll these products, which have reached a very high state of perfection of design, workmanship, and flexibility.

These mills operate at extremely high tonnages with very low labor costs, with very low maintenance costs, and practically no interruption due to mechanical defects. There are still a few instances in two or three steel plants in the United States where one new mill of the aforementioned late type, of proper size and with the proper arrangement, can replace three or four existing old mills of the type first described, and roll an equal amount of tonnage with probably 25 per cent of the labor, 60 per cent of the power, and 75 per cent of the fuel now required.

During the last three years there have been a few installations in Germany of merchant mills arranged very much the same as the late American mills. This has resulted from studies by German engineers and operators of American mills and methods for the same type of product.

Rod Mills

As in the case of merchant mills, the United States leads Germany today in production of rods per mill per shift. Most of the plants in the United States operate with fewer men per ton of output than in Germany.

Rod mills here are generally of two types, the "Garrett" and the "continuous." The tonnage per shift and per month of the same size of rods is practically the same on the two types of mills, but the labor costs on the Garrett type is much higher. All of the later installations have been of the continuous type, on which it has been possible to finish No. 5 rods (0.207 in.) at a speed as high as 3600 ft. per min. With the Garrett type mill the limit in speed due to the hand sticking on the last pass is about 1500 ft. per min. Although the delivery speed of the continuous mills is about 2.5 times that of the Garrett mill, the output per unit of time on the two types is the same. On the continuous mill only two strands can be run at one time, but on the Garrett type it is possible to keep four rods in the finishing stand at all times.

In Germany just recently there have been one or two installations of rod mills somewhat different from either the American Garrett or continuous type, in which billets are roughed on a continuous train and are then rolled on a series of independently driven intermediate stands somewhat after the fashion of the Garrett mill. These have proved quite successful and will undoubtedly lead to some modification in layout and design better adapted to German demands for tonnage and labor conditions.

Sheet Mills

The United States leads the world in total production of sheets and very greatly excels in the manufacture of high-grade sheets for automotive construction, deep stamping, and drawing purposes.

Many factors have entered into the process of manufacturing high-grade sheets as of today, among which may be mentioned the quality of steel furnished the sheet mills, the surface of the sheet bars, the automatic control of temperature in pair and sheet furnaces, the operation of the mills on the "loose-screw" system, the methods of cold rolling, the "normalizing" of sheets, and, where necessary, leveling by mechanical means.

In Germany there is but little demand for high-grade sheets, and the production as a whole is comparatively small. Therefore, Germany has not been in a position to follow, only in a modest way, the methods perfected in the United States.

In both countries the roughing and finishing is performed in much the same manner. The number of men per crew is practically the same, but mechanical doublers have been in use in the United States for some few years. This is a device which can be operated by unskilled labor, used to double the sheets from twos into fours, threes into sixes, or fours into eights, and replace a very highly paid doubler with a cheaper operator. This reduces the labor cost per ton and to a certain extent affects the production in favor of the mill equipped with mechanical doublers.

In the United States the demand for sheets for automotive and deep-stamping purposes, heretofore supplied from the ordinary sheet mill by more or less special processes, is gradually being replaced by strip. Whereas until six years ago the widest strip then rolled was approximately 14 in., the widths were increased up to 24 in. In the early part of 1926, and since, mills have been developed for the rolling and coiling of strip up to 48 in. wide.

These mills are usually of the four-high type with driven small-diameter working rolls backed up top and bottom by larger-diameter idle rolls, arranged in continuous formation. It is possible to roll 30 in. wide No. 16 gage, 36 in. wide No. 14 gage, and 48 in. wide No. 12 gage at finishing speeds ranging from 600 ft. to 1000 ft. per min. The same type of four-high single or continuous mills is beginning to be successfully used for cold-rolling strips to final gage. It remains to be learned just how far this type of continuous hot and continuous cold rolling will affect the present methods of manufacturing sheets.

Tin Mills

As was the case in connection with sheets, the United States leads the world in the production of tinplate. In 1928 the production was 1,970,000 tons, being approximately 60 per cent of the total world's production. The accompanying table gives the production of tinplate in Germany, the United Kingdom, and the United States.

TINPLATE PRODUCTION IN TONS

Year	United Kingdom	Germany	U. S. A.	Total 3 countries	Per cent U. S. A.
1891	....	....	1,000	.....	..
1900	....	....	303,000	.....	..
1910	817,000	57,000	773,000	1,647,000	46.9
1920	608,500	31,000	1,437,000	2,076,500	69.2
1926	580,000	97,500	1,782,000	2,459,500	72.4
1927	750,000	130,000	1,657,000	2,537,000	65.3
1928	....	....	1,970,000	.....	..

On account of the high cost of labor compared with that abroad, the United States has been forced to a high production per unit of equipment to reduce the fixed charges and to offset, partially at least, the increased cost of labor. In Wales, Spain, and in some plants in Germany tinplate is rolled today in packs of eights from one bar, doubled four times and heated five times. The latest mills in the United States roll tinplate from a pair of bars doubled on a mechanical doubler into fours after the first operation, drawn in fours and doubled into eights in the second operation, and finished in eights as the last operation with a total of three heats.

Abroad, a mill consists of a rougher and finisher in almost all cases, except in a few instances in Germany, where a single stand of rolls is used for roughing and finishing. In Wales up to 1922 a crew consisted of four men. Later on, two men were added to the crew, with no increase in production whatever. The same sized crew holds for Spain and on most mills in Germany. This crew of six men, on the average range of sizes and gages of tinplate, produces per mill per shift of 8 hours about 60 to 65 boxes or three tons.

In America there are two types of tin mills. The single-roll mills are operated some by the four-part system today where mechanical doublers have not yet been installed, and by the three-part system with mechanical doublers. The two-roll, three-part system has mechanical doublers for both the rougher and the finisher, one stand doing the complete roughing and the other rolls the fours and the eights.

The crew for a one-roll, three- or four-part-system mill in the United States consists of eight men, and a crew for a two-roll three-part-system mill consists of 16 men. The output per mill, per shift of 8 hours on the single mill will vary from approximately 4.5 tons per mill with the four-part system to 5.5 tons per mill with the three-part system. The production on the two-roll, three-part system will vary from 9.5 to 11 tons per shift.

One plant in the United States has recently installed a four-high continuous hot mill for the rolling of strip to replace the roughing of pairs previously required. The plant consists of mills of the two-roll, three-part system with mechanical doublers. The success of operation by this method is being watched very carefully by the tinplate manufacturers in the United States.

Tube Mills

Tube mills can be classified as three kinds, butt weld, lap weld, and seamless. In the manufacture of pipe by the butt-weld process, the United States is far ahead of Germany in tonnage and equipment for its manufacture. Investigation has shown that Germany has very few butt-weld mills and all are of antiquated design and operated very inefficiently. It has only been during the winter of 1928 and 1929 that the first installation of a butt-tube mill equivalent in design, capacity, etc. to those in common use in America has been installed.

In regard to lap-weld pipe, practically none is made in Germany by this process. Lacking the facilities to manufacture seamless tubing the United States necessarily had to develop a method of manufacturing tubes of a size larger than could be made by the butt-weld process. Tubes by the lap-weld process have been manufactured here in diameters up to 24 in. and larger.

In regard to the manufacture of tubes by the seamless process Germany has always led the world. The United States has been very backward in adopting this process. It was first tried out a few years ago for the manufacture of small tubes, principally boiler tubes where the maximum diameter was approximately 4 in. On account of the demands for seamless tubing in the oil fields in the United States, particularly for the deep wells in lower California and in some of the later fields in Texas and Oklahoma, the question of the manufacture of seamless tubing was very seriously considered by different manufacturers in 1924 to 1928.

In Germanv the process of manufacturing seamless tubing consists of first piercing a billet or ingot, and then finishing a tube of the proper outside diameter and wall thickness on what is called a "pilgering" mill. This is a very interesting process calling for very special equipment, but which produces a tube of extremely good quality so far as physical strength is concerned.

In 1926 and 1927, two steel companies in the United States imported German-made equipment for the manufacture of seamless tubes by the piercing and pilgering method. Previous to this date, however, there had been developed a different type of mill for the manufacture of tubes up to 6 in. in diameter. A billet or ingot was pierced, and in some cases given a second piercing, fairly close to the finished outside diameter, and then rolled to outside diameter and to proper wall thickness in a special mill over a mandrel on the inside of the tube. This is called the "automatic" mill.

It is believed that the method of piercing a solid billet or ingot, as the preliminary step for the manufacture of tubes by either the pilgering or automatic process, has not yet reached the limit of possible perfection. There is being installed at the present time in Germany a new design of piercing mill which has been tried out experimentally, and under such conditions has warranted the expenditure for a proper installation. It is claimed that, if successful, this particular type of piercer will be able to pierce in one operation to a much thinner wall thickness than has been heretofore possible by either the Mannesmann or Stiefel process, and that the variation in thickness of wall at any point in the tube will be very greatly reduced.

Discussion

H. J. Freyn.[2] The paper gives a very good and comprehensive comparison of the German and American steel-plant practice. Of course, the author was unable within the compass of the paper to mention every point of difference, but there is one that might be discussed. It is the essential difference in plant layout in the two countries, and while American plants as a rule show a very simple layout which allows for future expansion and simple and efficient transportation, a great many European plants lack a clear conception of the essential requirements of modern production methods. This is partially due to the fact that many of these plants are quite old, and that the very diversified product militates against the establishment of a clear-cut future program.

Another point typical of the general plant layout in America is that, in spite of its greater simplicity, it is more flexible as to tonnage produced. The curtailment of production to 50 per cent in the United States will not handicap the cost of production in as detrimental a manner as would be the case in Germany.

Another point that may be worth mentioning is the much larger diversity of the products that have to be made in the average German plant. This is due to the restricted market and to the earlier development of the European industry, which took place at a time when the change from the small private ownership to a larger concern had not taken place. The complication caused by the diversity of product results in a variety of mills, which cannot be used efficiently. This weakness has been realized, and if there is anything remarkable in the German development of the last years, it is the trend toward specialization in the mills, brought about by mergers. It is the policy of the large companies to concentrate the rolling of rails and heavier structural shapes in certain plants, while others specialize, for instance, in plates and sheets exclusively.

On the question of coke plants, it should be noted that the Germans take less pains in making a high-grade coke than do the Americans. This is caused by the fact that coke plants and blast furnaces are independent, and that the blast-furnace man has no control over the coke plant. The by-product coke plants are very frequently located at the coal mines and are operated for the highest yield of by-products, rather than for quality of metallurgical coke.

In regard to blast furnaces, it may be mentioned that the two latest German plants, those of Mannesmann at Huckingen and Krupp at Essen, have adopted the American skip hoist. Skip filling has also been used for many years at the Rheinstahl plants. There is an unquestionable tendency in Germany to abandon in future the complicated and expensive system of tub filling, and to resort to the much simpler method of double skip filling.

The method of blowing, mentioned in the paper, does not seem to be as common as might be inferred from the author's

[2] President, Freyn Engineering Co., Chicago, Ill.

statement. The two latest German plants use steam turbo blowers; moreover, some of the largest plants practice individual blowing exactly as is done over here.

One reason for the use of a common cold-blast main for several furnaces is the use of gas-blowing engines. The present large furnace productions cannot be met with single gas-blowing engine units. Moreover, the application of one single gas-blowing unit on a blast furnace is still somewhat hazardous. In addition, it is of course desired to operate the gas-blowing engines at the highest rating, and consequently at the best efficiency. Owing to the variable blast pressures, this can be done much more easily by having a minimum number of gas-blowing engines produce the blast for a number of blast furnaces, than to have each furnace blown individually by engines which may be operating at only two-thirds, or less, of their maximum capacity.

In regard to open-hearth practice, an essential difference between the two countries is the different layout of the charging and casting facilities. The superiority of the American arrangement is now being realized by a number of operators in Germany. The very keen interest in new open-hearth furnace designs in Germany is significant.

Whether with the advent of more efficient checker chambers the waste-heat boiler will disappear in America might be doubted. In Germany there is an increasing interest in waste-heat boilers, in spite of the low waste-gas temperatures that are being obtained with present efficient checker arrangements. This is due to the fact that a waste-heat boiler always presupposes the application of forced draft; the latter, however, is very desirable from an operating standpoint. It is possible that German development may not lead to the use of waste-heat boilers, but of recuperators, but it is certain that artificial draft with power-driven fans will become general practice.

The author's observations as to fuel economy in open-hearth practice hit the nail on the head. However, he neglected to mention that America is far ahead in the manufacture of high-grade steels in large furnaces.

In regard to the difference in operating practice of the two countries it may be said that open-hearth furnace operation, for instance, is very different in Germany under otherwise equal conditions. Consequently the yield up to the soaking pit is higher in Germany, while in the finishing mills it is higher in America. It is not certain which method is best, but it is to be hoped that these problems will be taken up by the operating men of both countries as having a very important bearing on the design of steel plants.

F. C. Biggert.[3] There is an old saying that comparisons are odious, but the writer feels that the author has made his comparisons with such fairness and allowance for controlling factors that no offense may be reasonably taken.

Having had some experience in designing steel-mill equipment for foreign use and having listened to the frequently ill-considered criticisms of American steel-mill men after they have visited foreign steel plants, the writer has been impressed with the very great care necessary in making such comparisons. In fact, he has come to the conclusion that, given identical conditions of natural resources, markets, and other controlling factors, the engineers of any advanced nation will, in a short while, arrive at solutions identical in all major respects. The paper contains one of very few comparative statements where proper consideration has been given to the diverse operating conditions obtaining.

Cleaning, Distribution, and Uses of Blast-Furnace Gas

By WILLIAM A. HAVEN[1] and C. B. THORNE,[2] CLEVELAND, OHIO

In this paper the authors discuss blast furnace operation and show the relationship between blast-furnace operation and the amount and quality of blast-furnace gas produced. A comparison is given between methods and costs of gas cleaning, the distributive equipment and cost of distribution, application for various purposes, and the profit that can be expected from blast-furnace gas as a by-product.

THE BLAST FURNACE is the largest producer of by-product gaseous fuel of any of the metallurgical processes. Depending upon the quality of the raw materials, the efficiency of the furnace operation, and the analysis of the pig iron being produced, the quantity of gas produced per ton of pig iron will vary considerably, but for good practice in American blast furnaces, producing basic and bessemer pig iron from lake ores, without excessive use of scrap and burning an average grade of by-product coke, having, say, 11 per cent ash, 1 per cent sulphur, and satisfactory physical characteristics, the production will be in the neighborhood of 135,000 cu. ft. of gas per ton of pig iron.

Under such conditions the thermal quality of the gas will be about 90 B.t.u. per cu. ft. The total fuel value of the gas produced in making a ton of pig iron will be therefore about 12,150,000 B.t.u., which is slightly more than one-half of all the heat which can be developed by complete combustion of the coke charged in the furnace, and approximately one third of the heat value of the coal charged in the ovens. It will have a heat value equivalent to that of about 900 lb. of good bituminous coal.

The daily gas output of a 1000-ton furnace will have a fuel value equivalent to that contained in about 450 tons of coal. The most economical and advantageous utilization or disposal of such a large and valuable amount of by-product fuel has become one of the most important factors in the determination of pig-iron costs, and to this fact may be attributed the keen and widespread interest which has been taken in finding uses for blast-furnace gas which will yield a greater credit against production charges, and a realization of the necessity for greater efficiency in all gas-using devices.

Of the total gas produced a sufficient amount must first be reserved for heating the furnace blast to the highest temperatures which specific conditions will permit the operators to use. These will vary within a range of from 1000 to 1600 deg. fahr., the physical and chemical quality of the raw materials being the chief limiting factors. Herein lies the most common opportunity of gas conservation, for the increasing of stove capacities and stove efficiencies has lagged behind the movement toward larger furnaces with the result that in many cases too much gas is being used for this purpose. Not infrequently as much as 35 per cent of the gas produced is required for the stoves, whereas recent developments in stove design have made it feasible to meet the most exacting demands with a maximum of 25 per cent.

Another 30 per cent, approximately, can always be used for generating steam and power required for the operation of the furnace itself. This is often, however, its least profitable use. If the by-product coking process is employed and there are better uses for coke-oven gas, blast-furnace gas can be burned under the ovens. The furnace-coke requirements alone will absorb about 25 per cent of the blast-furnace gas. If an open-hearth steel plant and rolling mills are included in the picture, from 20 to 45 per cent can be used there, mixed with coke-oven gas as a substitute for producer gas or other fuel. For isolated furnaces the generation and sale of electric power is sometimes the only commercial outlet.

In Table 1 an attempt is made to picture an ideal distribution of the by-product gases incident to the production of a ton of basic pig iron at a blast-furnace and coke plant operated in conjunction with an open-hearth steel works and rolling mill. This is a purely theoretical set-up, but based upon results obtainable in practice with efficient equipment. The following assumptions are used:

TABLE 1 PRODUCTION OF BY-PRODUCT GAS INCIDENT TO THE MAKING OF ONE TON OF BASIC PIG IRON AND A SUGGESTED DISTRIBUTION TO OPEN-HEARTH STEEL WORKS AND MILLS

		B.t.u. content	Percentage of total B.t.u. in—Coal	Coke-oven gas	Coke	Blast-furnace gas
1	Coal charged in ovens	37,950,000	100.0	...	..	...
2	Coke charged in blast furnace	23,100,000	60.8	...	..	...
3	Tar at 9 gal. per ton	2,080,000	5.5	...	..	...
4	Motor benzol at 2.5 gal. per ton	338,000	0.9	...	...	...
5	Coke-oven gas at 11,000 cu. ft. per ton	8,350,000	22.0	100.00	..	...
6	Domestic coke	1,600,000	4.2	...	..	...
7	Coke braize	1,600,000	4.2	...	..	...
8	Unaccounted for losses	882,000	2.4	...	..	...
9	Blast-furnace gas	12,153,000	...	...	52.5	100.00
10	Blast-furnace gas to underfire coke ovens	3,095,000	...	...	13.4	24.48
11	Blast-furnace gas to stoves	3,040,000	...	...	13.2	25.00
12	Unaccounted for coke-oven gas	417,000	1.1	5.00	..	...
13	Unaccounted for blast-furnace gas	608,000	...	...	2.6	5.00
14	Coke-oven gas left for open hearth	6,140,000	16.2	73.50	..	...
15	Blast-furnace gas to open hearth	2,390,000	...	...	10.3	19.70
16	Coke-oven gas to shops and misc	625,000	1.6	7.50	..	...
17	Blast-furnace gas to soaking pits	2,920,000	...	...	12.6	24.02
18	Coke-oven gas to finishing mills	1,168,000	3.1	14.00	..	...
19	Blast-furnace gas to finishing mills	97,000	...	...	0.4	0.80

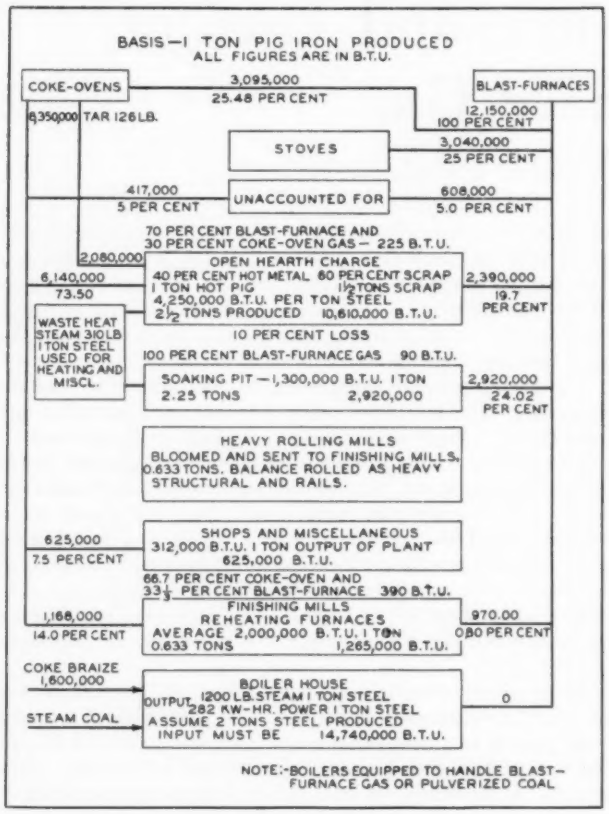
1800 lb. of furnace coke produced from a charge of 2814 lb. of coal at the ovens corresponding to a yield of 64 per cent.

11,000 cu. ft. of 540 B.t.u. coal gas produced per ton of coal charged.

1800 lb. of coke used per ton of pig iron produced.

135,000 cu. ft. of 90 B.t.u. blast-furnace gas.

Using Table 1 as a basis, a gas-distribution chart (see following page) has been drawn to show more clearly the relationship between the fuel and metal balances for such an operation.



The most profitable disposal of the gas can only be decided upon after a comprehensive study of the commercial possibilities which exist for the sale of coke, coke-oven gas, and power. Against contracts or the possibility of contracts for the sale of these commodities on a profitable basis must be weighed the value of the gas

Presented at the Fourth National Iron and Steel Meeting, Chicago, Ill., Sept. 24 to 26, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

GAS DISTRIBUTION CHART

as metallurgical fuel in the steel plant. This value in turn will vary greatly. It will be highest when the price of fuels which it may be used to replace is high. If the coal or other fuels are sufficiently low in price it may be very difficult to establish a case for blast-furnace gas from the standpoint of return on investment, notwithstanding the well-justified claims that it is a superior fuel for metallurgical uses.

The expenses involved in the cleaning and distribution of blast-furnace gas are considerable both from the standpoint of the equipment required and its operation. There is a lack of published data bearing on this phase of the subject which deserves the attention of operating men who are in a position to supply it. Reports on the cost of washing gas to various degrees of cleanliness have been anything but uniform and have been meager in detail, due, no doubt, in a large measure to the comparatively small number of installations in this country where "final cleaning" is practiced. This is true to an even greater extent as regards the cost of gas distribution.

With this thought in mind the authors have prepared for this paper, from their own records and from the most reliable information that could be obtained elsewhere, a comparison of the cost of cleaning gas in several types of washers now in use or being developed. They have also combined these costs in another series of figures with gas-distribution costs obtained in a similar manner in an effort to work out in a general way the net credits which will accrue to the furnaces after cleaning and distribution expenses are met. As a basis for the latter determination it has been necessary, of course, to assume an arbitrary range of prices for bituminous coal and of values for coke-oven gas. It is hoped that these calculations will furnish a basis for discussion which may bring out more extensive data along the same line.

In Table 2 is shown the cost of cleaning gas by several different methods giving the cleanliness expected in each case. The costs of final cleaning, i.e., from 0.15 to 0.008 grains per cu. ft. as accomplished either by disintegrators or Cottrell precipitators are shown in the table, but since the wet Cottrell method in this country is yet to be tried out on a large scale, all subsequent uses of the cost figure of final cleaning are on the basis of those obtained from disintegrator operations. No charge has been made for water in these costs other than the expense of boosting the water pressure at the washers. Make-up water for gas-washer pumps is in most cases the cooling water from the furnaces which, it is assumed, has already been charged against the operation of the latter.

All gas used for underfiring coke ovens or at open hearths and steel-heating furnaces must be cleaned to the dust content obtainable in the old-fashioned Theisens, in disintegrators or Cottrell precipitators. The question of the degree of cleanliness most profitable for use in stoves and boilers is a much disputed one, although the majority of operators in this country would probably desire gas for these purposes having not to exceed 0.2 grains per cu. ft. Until recently it was generally considered that the expense of cleaning finer than this was not justified except for gas-engine use.

Assuming that 25 per cent of the total gas produced is used in the stoves, Table 2 will show that the cost of washing gas for stoves to 0.15 grain per cu. ft. amounts to 1.179 cents for each ton of pig iron produced, and for final cleaning of this much gas

TABLE 2 COST OF CLEANING BLAST-FURNACE GAS

Type of cleaner	Tower washer	Two-stage McKee	Feld McKee	Disintegrator	Wet Cottrell	Disintegrator plus tower	Wet Cottrell plus tower
Cleanliness expected, grains per cu. ft.	0.3	0.15	0.10	0.008	0.008	0.008	0.008
No. units and capacity in cu. ft. per min.	1-75,000	1-75,000	1-75,000	1-30,000	1-40,000		
Investment costs							
(a) Cost complete	$50,000	$50,000	$70,000	$30,000	$55,000		
(b) Int. and dep. on above per day at 13 per cent	$17.80	$17.80	$24.90	$10.70	$19.60		
(c) Cost per 1000 cu. ft., cents	0.0165	0.0165	0.0231	0.0248	0.034	0.0413	0.0505
(d) Cost per ton pig iron (135,000 cu. ft. per ton), cents	2.23	2.23	3.11	3.34	4.59	5.58	6.82
Operating costs							
(a) Water g.p.m.	1665	1500	1250	250	70		
(b) Power to run (no boosting), kw.	0	37	90	200	20		
(c) Power required to pump water, kw.	62	54	45	5	1.25		
Total, kw.	62	91	135	205	21.25		
(d) Cost per day at 0.8 cent per kw-hr.	$11.90	$17.47	$25.90	$39.40	$4.08		
(e) Cost per day—lubricants	0.20	0.22	0.66	0.33	0.05		
(f) Cost per day—attendance	1.00	1.00	2.00	4.00	2.00		
(g) Cost per day—repairs and maintenance	1.00	1.00	2.74	2.00	1.00		
Total (items d-e-f-g)	$14.10	$19.69	$31.30	$45.73	$7.13		
Overhead 10 per cent on items (e-f-g)	0.22	0.22	0.54	0.63	0.31		
Total operating cost	$14.32	$19.91	$31.84	$46.36	$7.44		
Cost per 1000 cu. ft. gas, cents	0.0133	0.0184	0.0295	0.107	0.0129	0.1203	0.0262
Cost per ton pig, cents	1.794	2.484	3.98	14.45	1.741	16.24	3.535
Total cost—operating plus investment							
Cost per 1000 cu. ft., cents	0.0298	0.0349	0.0526	0.132	0.0469	0.1618	0.0767
Cost per ton pig, cents	4.02	4.714	7.08	17.80	6.33	21.82	10.35

the charge will be 5.455 cents per ton of pig iron. In other words, it costs 4.276 cents more per ton of pig iron to use final-cleaned gas than it does to use rough-washed gas. Whether savings will accrue from the use of final-cleaned gas in the stoves which will justify this additional expense is debatable. The cleaner gas makes for better operating conditions by the elimination of sludge in the mains and burners, but except for these features satisfactory operation and a high degee of stove efficiency have been obtained with gas of moderate cleanliness.

If rough-washed gas is to be used, a primary cleaner of the two-stage McKee type will supply gas of greater cleanliness than ordinary tower washers, and at the same time reduce the load on the secondary cleaners with a consequent saving in power as compared with that which would be necessary were only tower washers used for primary cleaning.

In explanation of Table 3 it must first of all be pointed out that no attempt has been made to evaluate the fuel economies which may attend the substitution of blast-furnace gas for other fuels. In the application of mixed gases to open-hearth practice this fact is of great importance. Remarkable reductions in fuel consumption are said to have followed this innovation at several plants.

TABLE 3 EFFECT OF CLEANING AND DISTRIBUTION EXPENSES UPON VALUE OF BLAST-FURNACE GAS AS COMPARED WITH STEAM COAL, PRODUCER GAS, AND COKE-OVEN GAS

		(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
					Cost of cleaning and distribution				
Purpose for which gas is used		Cost of coal	Cost of coal fired	Gross value gas before cleaning and distribution	Primary cleaning 0.15 grain per cu. ft.	Final cleaning 0.008 grain per cu. ft.	Distribution including boosting	Total	Net comparative value after deduction of cleaning and distribution expenses
		Dollars per ton	Dollars per ton	Cents per M. cu. ft.	Cents per M. cu. ft.	Cents per M. cu. ft.	Cents per M. cu. ft.	Cents per M. cu. ft.	Cents per M. cu. ft.
Primary washed gas as substitute for steam coal of 13,000 B.t.u. value	289,000 cu. ft. blast-furnace gas, 90 B.t.u. = 1 ton coal	2.50	3.00	1.039	0.0349	....	...	0.0349	1.004

Final cleaned gas as substitute for steam coal of 13,000 B.t.u. value	289,000 cu. ft. blast-furnace gas, 90 B.t.u. = 1 ton coal fired	2.50	3.00	1.039	....	0.1618	...	0.1618	0.877
		3.50	4.00	1.384	....	0.1618	...	0.1618	1.222
		4.50	5.00	1.729	....	0.1618	...	0.1618	1.567
Final cleaned gas as substitute for producer gas. Gas coal at 13,500 B.t.u.	255,000 cu. ft. blast-furnace gas, 90 B.t.u. = 1 ton coal fired	3.00	4.47	1.753	....	0.1618	0.536	0.6978	1.055
		4.00	5.47	2.140	....	0.1618	0.536	0.6978	1.442
		5.00	6.47	2.537	....	0.1618	0.536	0.6978	1.839
Final cleaned gas as substitute for coke-oven gas	6 cu. ft. blast-furnace gas = 1 cu. ft. of coke-oven gas at 540 B.t.u.	CO gas at $0.10 per M. cu. ft.			1.667	0.1618	0.536	0.6978	0.970
		CO gas at $0.20 per M. cu. ft.			3.333	0.1618	0.536	0.6978	2.630
		CO gas at $0.30 per M. cu. ft.			5.000	0.1618	0.536	0.6978	4.303

The item, designated as "Cost of coal fired" (Item 2), represents the delivered cost of coal plus 50 cents per ton of coal for boiler-house expense in the case of steam coal or plus $1.47 per ton conversion charges in the case of producer coal. The latter charge is made up of operating expense or cost above coal, estimated at $1.255 and $0.215 for interest and depreciation charges. The latter are taken at 13 per cent on an investment of $29,000 for each producer of 4000 lb. coal per hour capacity.

Item 6 is an estimate of interest, depreciation, and operating charges on the distribution system which will include gas mains, gas holders, boosting equipment, mixing devices, etc. The rate is at 13 per cent for interest and depreciation plus 2 per cent for operating expense on an investment which is taken at $17,850 per M. cu. ft. per min. capacity. It also includes a charge for boosting the gas pressure after washing of 0.0256 cent per M. cu. ft.

Although this cost of distribution seems high it should be kept in mind that in many cases the point of consumption is remote from the furnace plant. The estimates given are for a completely equipped installation and are substantiated by actual costs from one or two of the few plants which have been built. As there is likely to be a wide variation in distribution costs among different plants due to their topography, arrangement, and size of units, no exact figures can be given for the cost of distribution at any given plant without first making a careful survey of the property and a study of its requirements.

Table 3 will confirm the generally known fact that by far the most profitable use for blast-furnace gas is for underfiring coke ovens, provided a reasonably good price for coal gas can be obtained. Unfortunately many of the old by-product ovens are not equipped to burn blast-furnace gas and the change-over in such cases will probably await the normal rebuilding period unless the demand and the prices obtainable for coke-oven gas are unusually good.

It will be noted that the cost of final cleaning for boiler gas is 0.127 cent per M. cu. ft. higher than for rough-washed gas. Increased boiler efficiency or decreased boiler operating costs of about 13 per cent would seem necessary to justify this procedure.

As a substitute for producer gas the justification must come largely from the reduction in fuel consumption which has been briefly mentioned before or in the betterment of metallurgical practices. This subject has been covered recently in technical papers by others having first-hand information. The authors will attempt, however, to summarize briefly some of the reports from operators who have used blast-furnace gas in open hearths, heating furnaces, and under coke ovens.

Within the past two years there have been a number of large-scale applications to coke ovens, open hearths, and heating furnaces with uniformly good success from an operating standpoint. In the modern combination regenerative-type coke ovens it is asserted that the longer and less-intensive flame of blast-furnace gas will accomplish more uniform heating of the oven walls. Furnace men using coke from such ovens have testified to its excellent quality. Straight blast-furnace gas has also been used as a direct substitute for producer gas in soaking-pit furnaces. It is also obviously suitable for direct use in box annealing furnaces or other types of furnaces where comparatively low temperatures are sufficient.

Mixed with varying amounts of coke-oven gas, blast-furnace gas has been a pronounced success as a fuel for open-hearth furnaces and for heating furnaces generally. The results obtained in the open-hearth departments of the Steel Company of Canada and the Wisconsin Steel Company have been particularly interesting, inasmuch as in one case the air only is preheated, while in the other both air and gas are passed through the regenerators. There are advantages and disadvantages in both of these methods which have been widely discussed in technical papers, with no lack of advocates for either. Preheating of the gas seems chiefly desirable to produce luminosity of the flame which it accomplishes by the breaking down of the hydrocarbons which are contained in the coke-oven gas. Luminosity is useful in working the heat both as a visible indication to the melter of the furnace temperatures, and also, it is claimed, as an aid in transferring heat to the bath. It is said to be a deterrent of foaming and consequently of particular advantage in working heats in which a high percentage of pig iron and ore are used. The opponents of gas preheating discount the advantages and necessity of luminosity and

contend that they are outweighed by the safety and simplicity of a system in which gas preheating is entirely avoided. If luminosity is desired, it can also be secured by the addition of a small amount of tar.

For the purpose of this paper, it is sufficient and significant to note that remarkably good results have been obtained by both methods, not only in fuel consumption but in tonnage output, quality of steel, and life of refractories. Less than 5,000,000 B.t.u. per ton of steel has been consistently accomplished. The thermal value of the gas may be varied more or less, but generally averages about 225 B.t.u. per cu. ft., corresponding approximately to a mixture of 30 per cent coke-oven gas and 70 per cent blast-furnace gas.

In heating-furnace practice equally satisfactory performance has been reported from the use of mixed gases, and the advantages that were to be expected from having a gaseous fuel adjustable in heating value and flame characteristics to the requirements of each kind of steel to be heated have been borne out in actual practice.

The generally satisfactory results which have attended the use of blast-furnace gas in the steel plant are due largely to the fact that it is ideally fitted for mixing with coke-oven gas; its thermal value being about 90 B.t.u. per cu. ft. and that of coke-oven gas about 540 B.t.u., their combination in varying proportions will cover the range of flame temperatures which is needed for most metallurgical purposes. The large quantity of inert constituents in blast-furnace gas make it particularly useful where mild soaking temperatures are needed, while the admixture of the richer coke-oven gas in the proper amount makes it possible to increase the intensity and cutting quality of the flame to any desirable extent.

This complete or partial substitution for coke-oven gas has the further advantage of conserving the supply of the latter and making it available for a much wider application in the steel plant than has formerly been possible. In the new steel plant which the authors' firm is designing for the Russian government, in which the production of steel will be about equally divided between the Bessemer and open-hearth processes, it is expected that the firing of coal will be unnecessary except for generating about 57 per cent of the plant steam requirements.

Where the extension of the use of blast-furnace gas for existing plants is under consideration, the cost of adapting the coke ovens and furnaces to the use of the new fuel must be taken into account, and, together with the expense of cleaning and distributing the gas carefully, compared with the economies which may be obtained. The latter, as indicated, will depend upon the cost of other fuels, the possibility of profitable sale of coke and coke-oven gas, and the improvement in metallurgical practices that may follow. But it is safe to predict that in many American plants where surplus blast-furnace gas is now being used exclusively in boilers, a careful study of all the conditions will reveal that it can be applied in a large measure to other purposes with a substantial return upon the investment required for making the change.

Discussion

F. H. Willcox.[3] This excellent paper is suggestive of measures that the steel industry will have to put into effect. The industry today is based on production. Since 1910 it has grown from about 49,000,000 tons of pig and ingots to 94,000,000 tons of pig and ingot output. Potential capacity is probably 120,000,000 tons of pig and ingot per annum. It is an industry of small annual turnover and high capital expense. The cost of installing steel-plant capacity is nearly twice as much today as it was 25 years ago. Then, 1.9 tons of ore and 1.7 tons of coal cost $9.30, as against $11.70 today. Pig iron sells for about the same price now as then. However, bars sold for $26 to $28 in that period, as against $36 to $38 today, and the same ratio obtains in rods, structural, plate, billets, etc. The proportion of cost in materials, labor, and supervision has changed little in this period compared with capital charges, which have doubled. It is difficult to escape a feeling that the steel industry in the last 20 years has installed units and capacity geared to the output and prices of boom times, and not too well adapted to the 70 to 85 per cent average production year nor to export of semi-finished material. It is also possible that as the size of units has grown, and as the cost of the plant per ton actually produced per year has doubled, the ratio of money spent for brains in analysis and promotion of better costs and practice, with less capital, material, and labor waste, has not kept pace. In spite of better wages than were paid 20 years ago, the standard of wages and living for men in the steel industry is not what it should be compared with men similarly employed in transportation, building, or general commerce, not to mention luxury trades.

The industry being one with this background of development, of high capitalization, with moderate profit and wages, and finally, of no net result in the lowering of prices that must be charged, it is worth inquiring whether money could not be profitably spent for a greater degree of what one may call "general staff" work. The paper mentions a field earlier suggested by Cutler, Leahy, and others, but few plants on this continent are actually doing work in this line. It concerns not only fuel economy, but faster melting and heating, better practice on yield, and improved uniformity of product and acceptance. Analysis of costs has made surprising disclosures, almost warranting the guess that while total costs, or production costs, are known, too few know the actual detail structure or cause of costs, from ore or coal yard to delivery of steel to customer. Adoption of equipment is not infrequently decided upon on the basis of the best type of sales effort or use elsewhere under different conditions of application.

Transportation, maintenance methods, application of more durable and suitable materials, and even time studies are profitable fields. Undoubtedly too much money has been spent in super-power plants in steel works.

To summarize, the writer is inclined to think that study along the lines of these fields is more in order than the 20-year policy of bigger units, more output, and increased capital costs. The next 20 years, if not 10, should somehow yield more in the direction of higher pay for the men in the industry and lower rather than higher prices for the product, both export and domestic.

T. A. Lewis.[4] The paper presents very clearly the heat balance of a typical steel plant which, in turn, has led on to the discussion of very pertinent problems on blast-furnace gas. Blast-furnace gas, as indicated in the paper, is available in very large quantities and must be handled as quickly as generated, unless tremendous storage capacity is available. In this country, this gas has usually been consumed in blast-furnace stoves, boilers, and gas engines. In recent years we have been giving more thought to further utilization of this fuel for better conversion values. The development of this low-grade fuel has come along only recently in this country, as hitherto the economics of the situation was not sufficiently pressing to force the issue. However, the developments and economies derived in recent applications have proved their justification, with the result that the distribution of this fuel is being extensively made in many plants.

Each plant must be studied carefully to determine the economic

[3] Vice-President, Freyn Engineering Company, Chicago, Ill.

[4] Combustion Engineer, Bethlehem Steel Company, Bethlehem, Pa.

use. A heat balance must be made, and this in turn must be balanced with the return on the investment cost of the total system required to utilize this fuel. Blast-furnace gas has proved its value in open hearths, coke ovens, soaking pits, and reheating furnaces, as well as in many other types of furnaces; consequently, this fuel can replace fuel that is usually higher priced, as well as eliminating the conversion cost (such as gas producers with high cost of gasification).

The uses of blast-furnace gas involve cleaning and distribution costs. The cost of cleaning is dependent upon the degree of cleanliness desired, which in turn determines the type of cleaner to be used. The cost of distribution is dependent upon the uses, as well as distances of consuming departments from the blast furnace.

In the general distribution, in the authors' paper, approximately 30 per cent was alloted for generating steam and power for the operation of the furnace itself. With the developed uses of blast-furnace gas, this figure is too high, as no more than 14 to 20 per cent should be used. The lower figure of 14 per cent is for the gas-engine blowers and the 20 per cent for the steam (modern) units. Undoubtedly the use of blast-furnace gas in the coke ovens is very desirable, as in turn this releases a rich coke gas which can be distributed easily and cheaply because of its high calorific value and its relative low density. Furthermore, this gas is especially desirable on the higher temperature operations in the steel plant, or it can be sold at a fair profit to the public gas companies. The domestic demand for coke-oven gas is increasing yearly. This is economically sound, and the use of coke-oven gas for such purposes should be encouraged.

After the stoves and blowing units have consumed their requirements, over one-half of the blast-furnace gas is available for other purposes. The desirable units to which it should be applied are open hearths, coke ovens, soaking pits, miscellaneous furnaces, and boilers.

The authors have drawn up, in a concise form, a cost sheet of blast-furnace gas cleaning by various types of cleaning equipment. A pertinent question is brought out as to the justification of going to the additional expense in cleaning gas better than 0.15 grain per cu. ft. From the table presented there is a differential price of 4.276 cents per ton pig iron more for cleaning the gas from 0.15 to 0.008 grain per cu. ft. Study of cost sheets indicates there is justification of this additional expense. We do not have sufficient data in this country as we have not had clean gas long enough to prove the point. However, we can be guided by the practice of Europe, which has had a fairly good backlog of experience with the cleaner gas. The more experience most plants have had with clean gas, the greater is the demand for even cleaner gas. The efficiency of stoves is somewhat higher with narrow checkers than standard checkers with the same heating surface. More heating surface can be stored in unit volume with narrow checkers, which means fewer stoves per furnace and, consequently, added efficiency and less equipment.

For the most economical furnace operation, it is desired to have the highest stove line heats that the charge will permit. Consequently the stove heats will be raised. The life of the stove is influenced by the temperature in the stove and the cleanliness of the gas. The dirt in the gas, particularly the alkaline salts, fluxes with the brick of the stoves, particularly in the combustion zone, dome, and first section of the checker chamber, thereby reducing the fusion point of the brick, which in turn causes disintegration and slagging. This means higher maintenance and more frequent periods of shutdown. Furthermore, dirty gas carries mechanically entrained moisture in excess of saturated clean gas. This means lower efficiency. For stoves with small checkers the gas should be cleaner than 0.02 grains per cu. ft. The higher heats of blast should mean even greater cleanliness. Stove costs for long periods would warrant the advantages of the higher-priced clean gas, particularly where the gas saved could be used to replace fuel elsewhere. Since there is a greater demand for better stove practice, more care is given to better design. With the advent of narrow checkers and clean gas, designs have been developed that will give the desired velocities at the various sections of the stove. There are many ways of accomplishing this. The design with changing sizes and openings is usually termed the zone system. This zone system adapts itself to the physical loss of heat transmission in the upper zone to radiation and to convection in the lower zone.

The radiant-heat transmission increases with the thickness of the gas stream (in B.t.u. per sq. ft. per hr.), which means wide openings at the top; while the convection-heat transmission increases with the velocity due to turbulence, which means a larger number of small openings. Heat penetration is a function of temperature; therefore the thickness of the upper part is greater than the lower colder part. This is comparable with the practice in modern boiler design. In the straight-tube boiler the lower banks of tubes have a large tube diameter with a wide pitch, while the upper cold banks have small diameter tubes with narrow pitch.

As pointed out by the authors, no attempt was made to evaluate the advantages of fuel economies of clean blast-furnace gas over other fuels. This is a very important point with respect to the application of mixed gas for metallurgical furnaces. The operation of a mixed gas furnace or partly mixed gas with producer gas, in comparison to a straight producer gas furnace, is very pronounced. The soot formation in a producer-gas furnace reduces the life of the furnace and makes it considerably less efficient as becomes older. The clean mixed gas application gives longer furnace life and sustained fuel economy. This combined with the elimination of the producer conversion costs will go a long way to justify the use of blast-furnace gas and its attendant cleaning and distribution costs. In the case of underfiring coke ovens, it is essential that this gas be very clean as it is expected to have ten or more years of uninterrupted service.

In the case of soaking pits and other smaller furnaces, the fine degree of cleaning that is needed in coke ovens is not so essential, although the required degree of cleanliness is determined by the layout of the distribution system.

Reference has been made to different methods of application of mixed gases in the open hearth; namely, preheating of both gas and air as one method and only preheating of air for the other scheme. With reference to the type where the coke-oven gas is preheated to a degree sufficiently high for decarbonization of the hydrocarbons for luminosity, great care should be used in cooling down the blast-furnace gas to reduce the water vapors that otherwise would be carried over and mixed with the mixed gases. The effect of luminosity would be neutralized by the dissolving of the C particles by water vapor.

$$C + H_2O = CO + H_2$$

These conditions have existed, and the differential luminosity has been made up with liquid fuel.

Reference has been made to the advantages of the substitution of blast-furnace gas for coke-oven gas. This does enable a plant to reduce the outside purchased fuel. The ideal steel plant, from a fuel viewpoint, is the one which confines to the coke ovens all the fuel necessary to operate the plant. This is done in some plants. However, the character of the plant determines how far this can be accomplished.

FEODORE F. FOSS.[5] It was said that the world does not need to be so much informed as to be reminded. From this point of view the paper is valuable. It seems that American iron-masters should be constantly reminded that the fuel utilization in their plants is far from being ideal. In very many plants at least it has not yet reached a more or less satisfactory level. If we take as a basis of production sheet bar or rail and calculate fuel consumption per one unit of this product, we will find that after having delivered to coke furnaces 1.35 tons of coal (13,000 B.t.u.) we should operate the plant only on gases from coke ovens and blast furnaces, without any additional fuel. Such results have been obtained already on practice by several German plants producing open-hearth steel. Plants equipped with basic Bessemer converters lower fuel consumption to one ton (and even a little less) of coal per one ton of finished product. In its endeavor to eliminate use of coal from all intermediate operations one large steel company near Duisburg went so far as to introduce electric traction on all railroads of their plant, receiving electric current from central power house. Nearly the same ratio of fuel consumption is obtained in best Luxemburg, Belgian, and some French steel plants recently acquired from Germany. Older French plants use from 2.5 to 3.5 units of fuel per ton of finished product. Most up-to-date American plants show fuel consumption of about 2 to $2^1/_2$ units per one unit of finished product, and the average for all plants seems to exceed 3 units. The worst results are observed in Great Britain, where a figure of $4^1/_2$ to 5 units is encountered. We know that there is a great lack of integration in the British steel industry.

All that confirms the rather old idea on what constitutes the most profitable unit in the art of steel making. A long time ago it was shown that a unit of the iron industry should be understood as a plant, which begins with coke ovens, ends with rolling mills, and uses coal only for making coke. The skill of iron-masters and plant designers should be demonstrated in their ability of balancing out productive units in such a way as to achieve the best fuel utilization and an uninterrupted production. An explanation for the lack of attention paid by American iron men to the proper utilization of fuel could be found, possibly, in the fact that coal in this country is so abundant and cheap. On the average it is twice as cheap as in continental Europe. Nevertheless, the time will come, and it seems to be very rapidly approaching, when every component item of steel costs will be scrutinized and analyzed with regard to the possible economies.

Having that in mind, we should pay our utmost attention to blast-furnace gas, its quality, and uses. The authors say, "If the coal or other fuels are sufficiently low in price, it may be very difficult to establish a case for blast-furnace gas from the standpoint of return on investment, notwithstanding the well-justified claims that it is a superior fuel for metallurgical uses." There is no doubt, as they assert further, that "The most profitable disposal of gas can be decided upon only after a comprehensive study of the commercial possibilities which exist for the sale of coke, coke-oven gas, and power." But, as already said, no other fuel other than blast-furnace and coke-oven gas should be present in the modern steel plant. Therefore all our studies should be directed to the ways of utmost utilization of available gases and elimination of all other fuels which have to be bought. There have been several studies made of evaluation of blast-furnace gas based on B.t.u. content of gas and coal. It was shown that if the blast-furnace gas is used in gas engines with an electrical generator attached without waste heat boilers, the value of gas will be from 1.3 to 1.4 higher than the respective coal. If we have a gas engine for electrical generation with waste heat boilers, the value of blast-furnace gas will be raised to 1.5 to 1.6. If we turn blast-furnace gas into the gas-blowing engine with waste-heat boilers, the value of gas will be from 1.15 to 1.5 higher than the coal. In the heating of coke ovens the value of blast-furnace gas is as high as 1.8, and in open-hearth furnace mixed with coke-oven gas it gives the value from 1.5 to 1.8. Even under boilers blast-furnace gas, if supplied constantly, shows the preference above coal to the extent of 1.1 to 1.4.

Blast-furnace gas, as we all know, is dirty, and the cleaning of this gas deserves much more attention than has been given to it heretofore. In olden days and in some plants at the present time it was customary to divide the gas, with reference to dust content, in two different grades—one a clean gas or "machine" gas and another "furnace" or stove gas. It seems that with the view of attaining high efficiency from all the apparatuses of metallurgical plants we have to look at our stoves and furnaces as on precise and delicate machinery and give them fuel in the form most suitable and most profitable for operation. Only then can we expect high efficiency from our equipment. Applying this principle, some blast-furnace managers have achieved very high efficiency of heating stoves and use only from 25 to 20 per cent of blast-furnace gas for one ton of pig iron. In such cases stove checker-work was protected from excessive dust and from slagging of brick surfaces by alkaline particles contained in the blast-furnace gas dust. Very high thermal efficiency of stoves resulted, and the cost of stove cleaning became practically negligible.

Turning now to the cost of cleaning blast-furnace gas as shown on Table 2, we find that this table is rather incomplete. Data relating to some other systems of cleaning are lacking. Results of dry cleaning by using the Halberg-Beth process, and particularly by modern electric cleaning processes, are not given. It should be mentioned also that the figures of the gas cleanliness shown in the table are qualified as "expected" and not as "actually" obtained. We know that these two definitions often differ very markedly. Studying the results of different gas-cleaning methods, we find that by applying different methods of dry cleaning we may achieve a rather low cost with very high degree of gas cleanliness and a very low moisture content in the gas. So far as the writer knows, the electric gas-cleaning plant at Witkowitz Steel plant in Czechoslovakia, reducing the dust content in a cubic foot of gas from 1.92 grains to 0.002 grains, gives the cost of cleaning only as 0.08 cent per 1000 cu. ft. Electric installation costs a little higher than wet disintegrators and is quoted to be about $26 per 1000 cu. ft. per hour, whereas disintegrators cost about $21. It seems that when the demand for the *real* clean gas will come, the attention of blast-furnace men will be turned from the tower washer and the like to the disintegrator and particularly to electric cleaning.

With the results shown in Table 3 the authors contradict what they have said before in reference to the evaluation of gas and show that the most profitable use for blast-furnace gas is for underfiring coke ovens. They actually confirm the fact, which has been explained above, that blast-furnace gas is the real fuel for metallurgical processes and has its definite value in preference to coal and producer gas.

Further on the authors cite several examples of very economical use of blast-furnace gas in combination with coke-oven gas for the open-hearth process, showing that less than 5,000,000 B.t.u. per ton of steel has been constantly obtained. These results, again, confirm the opinion that if proper attention is paid to the quality of blast-furnace gas, ideal results of fuel utilization in the steel plants can be obtained.

J. F. SHADGEN.[6] Particular attention should be called to

[5] Assistant to President, Wheeling Steel Corporation, Wheeling, W. Va. Mem. A.S.M.E.

[6] Combustion Engineer, Smoot Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

combustion control. There are two kinds of controls on industrial furnaces: Human control supplied by customers, which has no visible capital charge, and machine control, which has to be installed and paid for.

Machine control (often erroneously called automatic control) has made great strides during the past decade, particularly in boiler rooms. Machine control has also been applied to metallurgical furnaces during the past few years. About 40 open-hearth furnaces and 13 heating furnaces are so far equipped with machine-control apparatus.

The results are most encouraging, as the increased fuel efficiency proves, and greater progress will be made during the next years as the experience accumulates.

Gas mixing is usually done by machine regulation, and 15 installations are operating successfully, mostly mixing blast-furnace gas and coke-oven gas. Recently, the dilution of natural gas with a lean gas broadened the importance of the problem.

The writer would call for investigation of the applications of machine control, as results conclusively prove their economic value.

H. A. Brassert.[7] In planning the distribution of blast-furnace gas for any given plant, it is of first importance to establish accurately how much surplus blast-furnace gas can be made available. The authors state that recent developments in stove design have made it feasible to meet the most exacting demands with a maximum of 25 per cent of the total gas. Our experience with stoves employing the graduated zoning principle shows that this maximum has been reduced to very much lower figures, in some cases as low as 15 per cent. Furthermore, as Mr. Lewis has pointed out, the assumption of 30 per cent of the gas being used to generate the steam and power for the operation of the furnace itself is excessive whether turbo blowers or gas engines are used.

Substituting the lower figures for the stoves and other blast-furnace requirements, nearly twice the amount is available for the other departments and enhances the importance of the subject. In addition we must consider that a minimum of gas should be used under boilers if metallurgical applications are available for its consumption.

Just how far one can go in decreasing the consumption of gas on the hot-blast stoves depends largely on the cleanliness of the gas and the first cost and savings. In any event the saving in gas must be accompanied by the ability to heat the blast to the highest degree which it is possible to use. Fortunately modern stove construction has permitted us to heat the blast to higher temperatures than ever before, in spite of the low consumption of gas, by zoning of the checker column, a subject which has been so well explained by Mr. Lewis. The extent to which the checker openings can be decreased depends on the cleanliness of the gas and the type of impurities in the gas. From results obtained in American operation the writer is of the opinion that it is not necessary to clean the gas to the authors' figure of 0.008 in order to use the most efficient type of stoves, which combines the most effective velocity in the different zones with turbulence. The results of stoves having very small checker openings in the lower zones have shown that the increased velocity maintained therein keeps these narrow passages purged. The extremely fine deposits are thereby swept out, an action assisted by the turbulence created by the staggered fillers. Stoves of this type have been in operation for a period of several years operating on gas which averages 0.02 grain per cu. ft., and they have remained perfectly clean, as revealed by recent inspection of the checkers made possible through banking of the furnaces.

The cleaning of the gas below 0.02 grain requires a large amount of additional power, as it can only be accomplished by machines running at increased speeds, and the power is approximately a function of the cube of the speed. It is questionable whether stove designs should be of a type requiring much additional expenditure for power, the authors have shown, when a gas containing 0.02 grain or below can be delivered to zoned stoves of high efficiency at an expenditure in power of only a fraction of that given in this paper. In Germany stoves containing smaller openings than we have used in this country and so constructed that they cannot be inspected or blown out are considered to require gas of a cleanliness which can only be obtained by the bag-house system, which cleans the gas to 0.003 or less.

A gas with 0.02 grain per cu. ft. is also clean enough to be sent to open hearths and mill heating furnaces, particularly since experience has shown that by the time the gas is carried a considerable distance through pipe lines with bends and water seals, etc., the cleanliness at the delivery point is generally 30 to 40 per cent less than if measured immediately behind the eliminator following the disintegrator. Disintegrators are operating today which deliver from 50,000 to 60,000 cu. ft. of gas per minute with a cleanliness of 0.025 and less at an expenditure of from 50 to 70 hp. From this and from horsepower required by other machines which clean the gas to an average of 0.006, we can safely deduct that to average below 0.02 grain, it will not require over 125 hp. for 50 to 60,000 cu. ft. of gas per minute with Lake Superior ore practice and producing basic iron.

Furthermore, the power cost at the average steel plant runs lower than the figures given in the paper, and if actual costs were substituted, together with the lower horsepower, the comparison as between finely cleaned gas and gas from Feld or McKee washers, as shown by the authors to contain 0.1 to 0.15 grain, brings the cost of the disintegrator gas containing but a small fraction of the dust to only 50 per cent above the costs of the former gas, which cannot be used in high-efficiency stoves or for metallurgical purposes.

For coke-oven heating and gas engines, gas below 0.01 is required, but it is a question whether it is more economical to clean all of the gas to 0.02 and reclean the coke oven proportion separately.

There is no question as to the many advantages of using mixed gas or blast-furnace gas for melting and heating. The advantages are not only expressed in a saving of B.t.u. consumed, but also in the better control of the operations. The ability to regulate the B.t.u. content of the gas is of the greatest advantage, both in open-hearth practice and in heating. The combustion of blast-furnace gas results in a long, mellow flame. It is free from sulphur and its combustion can be proportioned to a much finer degree than that of richer gases requiring larger air-gas ratios. The writer was impressed in Germany with the high development of the art of heating and the much lower amount of scale produced due to the maintenance of neutral flame conditions in the reheating furnaces.

The blast-furnace gas has its greatest value in the finer uses, namely, coke-oven heating, melting and reheating, and its lowest value in raising steam. Boiler plants, even if especially designed for efficient use of blast-furnace gas, cannot obtain as high an efficiency of the same rating by the use of blast-furnace gas as can be easily be obtained from the cheapest solid fuels. At most plants operating conditions will require the bleeding of a certain amount of blast-furnace gas through the boilers, but this amount should be the surplus above all other requirements. The cost of gasifying the coke in the blast furnace has already been borne by the pig-iron production, and a very ideal gas, especially desirable for metallurgical purposes, has resulted. The boilers should be the last place to consume this

[7] President, H. A. Brassert & Co., Chicago, Ill.

gas, and the burning of gas under boilers should be considered only as an equalizing means for the plant system. The development of highly efficient automatic controls has given us practical means for the finest regulation of combustion in metallurgical furnaces, as well as means for automatical substituting of blast-furnace gas for solid fuel under the boilers. The writer is convinced that very large savings can be obtained in the industry with a fuller appreciation of the high value of blast-furnace gas for metallurgical use.

F. H. Willcox. Answering questions, it can be said that open-hearth practice abroad uses a steeper port, a faster velocity, and much more regenerative volume than we use here with producer gas or oil. They run faster heats than we do and have a faster turnover. Of course, open-hearth practice over there is based more on 20 per cent pig and 80 per cent scrap, which is easier than our 50–55 per cent hot-metal practice. One can satisfy one's self of 17 tons per hour rates throughout the month on 100-ton furnaces, of 3,200,000 to 3,600,000 heat consumption on straight runs, and 4,000,000 to 4,400,000 for a month's run.

As to the degree of cleanliness of gas, there is always a tendency to edge too close to what seems to be the toleration limit. That has been true in the case of stove gas, and we know that a toleration based on one blast campaign is a misleading and costly error when applied to a 16- to 25-year stove life. Practice on coke ovens and gas engines has demonstrated the need of the highest degree of cleanliness. The same will be found to be the case in other applications. The difference between 0.01 grain and under and 0.05 grain and over is extremely little in cost of equipment and cleaning, but tremendously great in effect on heating surface.

As to the effect of moisture on radiant properties of flame, it is not uncommon to see Halberger or Cottrell gas used at temperatures of 100 to 140 deg. fahr., without apparent adverse effect. This would be about 35 grains of moisture per cubic foot.

Geo. E. Rose.[8] The chairman having remarked that there had been considerable experimenting done at the Wisconsin Steel Works with the use of mixed gas (blast-furnace and coke-oven gas) on open-hearth furnaces and that there had been developed at this plant a movable port which had been described in a paper by Rose and Washburn of the Wisconsin Steel Works' organization and having asked for a statement of the experience with the use of mixed gas and the movable port construction at the company's open-hearth plant, the writer will give it.

We are quite well pleased with our progress in the use of mixed gas as the fuel on our open-hearth furnaces. Necessity has been the mother of invention in our case in this respect. We were confronted with the problem of making use of the coke-oven gas from an additional battery of coke ovens that we were about to start building in 1928, and which we now have built; therefore, we began to experiment with the use of blast-furnace and coke-oven gas on our No. 1 open-hearth furnace early in 1928. The writer was somewhat opposed to this proposition of trying to operate our open-hearth department with this fuel, and therefore got a trip to Europe out of it. As you know, in Germany they have been using mixed blast-furnace and coke-oven gas as fuel on open-hearth furnaces for the past 12 or 15 years. They have had much more experience with it over there than we have here. They emphasize very strongly the necessity of preheating the mixed gas up to 1000 to 1200 deg. cent., which is approximately 1800 to 2200 deg. fahr., so as to crack up the hydrocarbons in the coke-oven gas.

This cracking up of the hydrocarbons increases the luminosity due to the carbon particles in the flame. It is not the luminosity itself that is so much desired, but rather the transmission of heat by radiation from the carbon particles in the flame. This is a point that is not fully emphasized in open-hearth practice in this country. It is not so much the direction of the flame that is desired in an open-hearth furnace as the quality of the flame. In fact, the writer does not believe that a flame can be directed from the end of the furnace over a bath 40 or 50 ft. long so as to keep that flame hugging the bath, except by means of having the flame what it should be in quality and density. In other words, the important things are the quality and density of the flame rather than the mere directing of it from the end of a furnace 40 to 50 ft. long.

Now, if there can be a flame sufficiently laden with carbon particles (molecular carbon, as it were) derived from the cracking up of the hydrocarbons in the coke-oven gas, we get an increased transfer of heat in the open-hearth furnace proper by means of radiation from the carbon particles in the flame. We must not forget that the intensity of heat radiation from a given source varies inversely as the square of the distance from the source; hence the advantage of the nearness of the luminous flame to the bath as compared with the roof from a radiation point of view.

This explains why the old-time open-hearth operator frequently found it necessary to go back to the gas-producer house and have his gas man put fresh coal into the producers in order to get his furnace to go to work, as he would express it. He needed the soot particles formed by the addition of fresh coal to the producers. He could not get the necessary transfer of heat from the blue gas that the producers were making, even though the gas might have been quite high enough in B.t.u. value.

We feel that our experience confirms that of the German open-hearth operators, that it is very necessary for good results that the preheat of the mixed gas be carried up to around 2100 to 2200 deg. fahr., so as to give the desired luminosity to the flame, which simply indicates its great ability to transfer heat by radiation from the flame.

Now, of course, this does force one to speak of the movable ports, because without the movable ports it is quite impossible to have a port with a sufficiently restricted aperture to give the necessary jet velocity to the flame in the burning end of the furnace, and at the same time give a large enough opening of the gas downtake in the opposite end so as to get sufficient of the products of combustion back through the gas-checker chambers to bring the mixed gas up to the required preheat for the cracking up of the hydrocarbons and thence the luminosity and heat transfer by radiation.

The movable port moves into the furnace over the gas uptake on the burning end of the furnace, giving the flame the necessary jet velocity, but on the other end, the movable port is out of the furnace, leaving the full opening of the gas downtake, so that by manipulation of the reversing slide valves in the flues from the gas and air checker chambers, 50 per cent or more of the products of combustion can be taken down through the gas downtake and out through the gas regenerators, thereby making it possible to get a much higher preheat in the mixed gas than in the air, if desired by the open-hearth operator. At any rate, the preheat in the mixed gas can be brought up to an average of 2100 to 2200 deg. fahr. very readily.

As stated in the first place, the Germans have had fairly long experience with the use of mixed blast-furnace and coke-oven gas on their open-hearth furnaces. They have a high fuel cost, comparatively speaking; that is, a ton of coal costs about as much as three and one-half to four men's daily wages, whereas in our case here in the Chicago district, a ton of coal and a laboring man's daily wages are about equal; hence one can see the emphasis that is put upon fuel economy in a German steel plant

[8] General Superintendent, International Harvester Company, Wisconsin Steel Works, South Chicago, Ill.

and how they endeavor to make the best possible use of fuel. As a matter of fact, inasmuch as their major process of steelmaking is that of the basic bessemer (or Thomas), they necessarily make considerably more pig iron per ton of steel than we do here with our basic open-hearth process, in which we use about 50 to 50 pig iron and steel scrap. With the basic bessemer process the yield is about 90 per cent; or, in other words, a ton of pig iron will make about $^9/_{10}$ of a ton of basic bessemer steel, whereas with us, with the basic open-hearth process, a ton of basic iron will make almost two tons of steel, depending on the percentage of steel scrap used in the charge. But inasmuch as they make 60 to 70 per cent of their steel by the basic bessemer process, they necessarily have much more blast-furnace gas per ton of steel than we have in this country at plants where the basic open hearth is the major process of steelmaking. Even though they have much more blast-furnace gas per ton of steel than we have, still they clean their blast-furnace gas to a greater degree and to a finer point than we do and use it much more efficiently and thereby get more out of it, especially in view of the high cost of fuel in their country. However, it would seem as though it always would pay to clean it and use it efficiently rather than to waste it.

Of course, we do not deliberately waste it at many plants in this country, but we do fail to clean it properly at many plants and use it under low-pressure boilers and in stoves of large checker construction, in which cases we use almost twice as much as would be necessary for the same results if the gas were properly cleaned and if the stove and boiler construction was of the type and kind that can be used and should be used with clean gas. Of course, it undoubtedly is a fact that the return on expenditures for cleaning blast-furnace gas and the efficient use of it would not be as great in this country as in Germany, where the fuel cost is much higher, but as against the inefficient use of it in a steel plant where it is otherwise necessary to buy power or additional fuel, the writer believes it will pay in every case to clean the gas thoroughly and use it efficiently.

Authors' Closure

It is very gratifying to note the interest taken in this subject, and the authors are greatly indebted to those who have so generously and capably contributed to the discussion.

The Application of Metallic Recuperators to Industrial Furnaces

By G. D. MANTLE,[1] PITTSBURGH, PA.

Increasing cost of fuels and the growing pressure of competition make apparent the necessity of heat salvage in metallurgical furnaces. The paper asserts that there are few industrial furnaces that cannot be made 20 per cent more efficient by the installation of heat recuperators. A properly applied recuperator may result in an increased efficiency of 50 per cent. The actual value of heat salvaged from the waste gases by recuperation or regeneration is little appreciated by the average engineer.

THE forest of smokestacks in every industrial center would be sufficient evidence, even to those who were not familiar with modern manufacturing processes, that fuel is one of the prime economic factors of today. It is in fact the major cost item in many industries, and its more efficient use is one of the most serious problems facing the largest industries of this country. This is evidenced by the appointment during the last few years in practically every large industrial plant of specially trained engineers with efficient staffs whose sole duty it is to ensure the more economical use of the fuel used in manufacturing processes. The importance of this field can be realized when it is remembered that there are several hundred plants in the United States today whose fuel bill, exclusive of that used for steam-generating purposes, well exceeds $1,000,000 per annum. There are few metallurgical or ceramic plants of any importance whose fuel bill will not reach a minimum of $10,000 per annum.

There are three obvious means of increasing the efficiency of the average industrial furnace: (1) The salvaging of some of the heat in the waste gases by means of either a regenerator or recuperator, (2) the provision of automatic means to assure combustion of the fuel with as nearly as possible the theoretical quantity of air, and (3) the reduction of radiation losses by the use of insulating materials and by strict limitation of the sizes of doors and openings to the minimum required by the character of the operation performed in the furnace. In the general run of industrial furnaces, the magnitude of the saving to be effected will be in the order listed.

In view of the growing interest in combustion and in fuel conservation, it is a little strange that it should be necessary to advance any argument in favor of recuperation. The sheer necessity of heat salvage is made plain by the always increasing cost of fuels and the growing pressure of competition in all industries. Even those best posted in the design and operation of industrial furnaces will, however, often admit their inability to discuss in detail the economics of recuperation, or even to calculate correctly the value of the potential saving.

It will doubtless surprise the majority of engineers and operators to learn that there are few industrial furnaces which cannot be made 20 per cent more efficient by the application of a recuperator and that there are many cases in which an increase in efficiency of 50 per cent is assured by a properly applied recuperator.

The actual value of the heat salvaged from the waste gases by recuperation or regeneration is so little appreciated by the average engineer that no attempt will be made to analyze or discuss the various types of recuperator or regenerator.

Benefits of Recuperation

Combustion is simply the chemical combination of the elements of the fuel with the oxygen in the air. Every fuel, therefore, requires a definite quantity of air, varying with its analysis, for its complete combustion. For instance, the average natural gas requires approximately 10 cu. ft. of air to burn 1 cu. ft. of gas. In fact, the air requirements of the average gaseous fuel approximate 1 cu. ft. of air per 100 B.t.u.

The actual attainable flame temperature of natural gas, with cold combustion air, under practical conditions, is approximately 2800 deg. fahr., and it is obvious that in order to attain this temperature, the 10 parts of air, including the 79 per cent of inert nitrogen, will have to be raised to the flame temperature. The heat required to raise the air for the theoretical combustion of 1 cu. ft. of natural gas to 2800 deg. fahr. is 548 B.t.u., or 54.8 per cent of the calculated heating value of the fuel, assuming a gas with a heating value of 1000 B.t.u. per cu. ft. It is again obvious that if the combustion air be delivered to the burners, or grate, at some temperature exceeding atmospheric, the fuel will develop more B.t.u. per cubic foot, per pound or per gallon, as the case may be, and that proportionately less fuel will be required to develop a given quanity of heat.

To utilize a fuel to full advantage in useful work and radiation would require that the waste gases leave the furnace at atmospheric temperature. In the furnaces under consideration, any such condition is an impossibility, by reason of the temperatures required by the operation performed. It is rarely that the temperature of the gases leaving metallurgical furnaces is less than 1000 deg. fahr., and metallic recuperators are in successful operation on furnaces with waste gases at 2600 deg. fahr. The sensible heat in the waste gases at these temperatures represents a sheer loss of from 20 per cent to 56 per cent of a fuel having a definite monetary value per 1,000,000 B.t.u.

This loss can be largely salvaged only by means of a recuperator, regenerator, or in extreme cases by a waste-heat boiler. To make this point even clearer, it will be shown that by the installation of a comparatively inexpensive recuperator, the effective heating value of the fuel used may readily be increased from the equivalent of 1000 B.t.u. per cu. ft. to 1350 B.t.u. per cu. ft., without change in the cost per cubic foot.

The recuperator in its simplest, but actually impractical, form resembles a fire-tube boiler. The waste gases would pass through

---

[1] Mantle Recuperator Division, Surface Combustion Co., Inc. Mr. Mantle was graduated with Bachelor of Science degree from the University of London, England. During the past ten years he has been successively Chief Engineer, A. W. Cadman Manufacturing Company; Director, Calorizing Company; President, Mantle Engineering Company, and District Manager, Surface Combustion Company, Inc., all of Pittsburgh, Pa.

Presented at the Iron and Steel Division National Meeting, Chicago, Ill., Sept. 26, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the tubes and the air would be baffled across them in the shell before being delivered to the grate or burners. In passing over the tubes the air would absorb heat from the waste gases and being delivered to the burners, or grate, would definitely reduce the quantity of fuel required to liberate a given quantity of heat.

The idea of recuperation is not new. It is difficult to trace its history. Patents on recuperators were issued in the United States more than one hundred years ago. The development of the recuperator in connection with industrial furnaces has been hindered (1) by lack of true appreciation of its value, (2) by the only recent development of a construction which could withstand the conditions encountered, (3) by the lack of a material which would withstand the temperature and air pressures required by modern combustion systems, and (4) by a lack of definite information covering the possible heat transfer from waste gases to air through an air-tight ceramic or metallic wall.

All these limitations have been overcome during the past few years and metallic recuperators are now available which may safely be guaranteed, not only as to efficiency and air tightness, but as to life under even abnormal conditions of industrial furnace operation.

General Effect of Preheated Air Upon Furnace Operation

The theoretical flame temperature of any fuel of known analysis can readily be calculated, but such calculations have, as the name suggests, a purely theoretical value, and are often misleading. The calculated flame temperature cannot be attained in practice and is far from being attained in the average industrial furnace.

The theoretical flame temperature of the rich fuels—oil, coal, natural gas, city gas, and coke-oven gas—ranges between 3600 and 3900 deg. fahr., whereas the actual flame temperature attainable in an industrial furnace with cold combustion air rarely exceeds 2600 deg. fahr. Raw producer gas at a temperature of 1200 deg. fahr., when burned with cold combustion air, has a theoretical flame temperature of approximately 3450 deg. fahr., whereas the attained temperature rarely exceeds 2500 deg. fahr.

This great difference between the theoretical and actual flame temperatures is due (1) to radiation from the flame to surrounding objects during combustion, (2) to the impracticability of burning any fuel in a metallurgical furnace with the exact theoretical quantity of air, and (3) by dissociation of the carbon dioxide and water vapor in the products of combustion. The effect of dissociation is, however, negligible in the operation of furnaces in connection with which metallic recuperators should be considered, and will not be further discussed here.

The effect of the depression of flame temperature by radiation to surrounding objects is a matter of increasing interest in furnace design. It has, however, no direct relation to recuperation, except that excessive depression can in many cases be corrected by the application of preheated air. The depression of flame temperature, due to an excess or deficiency of combustion air, has a direct bearing on the subject of recuperation.

In metallurgical furnaces it is generally desirable that the fuel be burned with a deficiency of air in order to protect the material which is being heated from free oxygen. The amount of the deficiency depends largely upon the operation being performed in the furnace. The material heated in the furnace may be such that a reducing atmosphere represented by as little as 0.1 per cent of carbon monoxide in the products of combustion will afford the necessary protection to the steel. In other cases, as in the reheating of packs or pairs for full finished sheets, it may be desired that an Orsat analysis shall show as much as 8 per cent carbon monoxide. In metallurgical furnace practice, excluding the open hearth, it is generally desirable that the amount of free oxygen in the flue gases be reduced to a minimum.

With the exception of the clean gaseous fuels, no method has been developed to proportion so accurately and mix so thoroughly the air and the fuel that the products of combustion will contain neither unburned fuel nor free oxygen. Neither, with the exception just noted, has any means been developed to maintain accurately a desired combustion condition other than theoretical under all conditions of furnace operation. It has been determined by a large number of actual tests that it is not uncommon in metallurgical furnace practice to burn the fuel with a 25 per cent excess of air and at the same time permit 12 per cent of the fuel to leave the furnace either completely unburned, in the form of smoke or soot, or partially unburned, in the form of carbon monoxide. If the furnace is fired with the richer fuels, and the operating temperature is 2200 deg. fahr., the fuel loss due to the excess air alone is approximately 10 per cent; and as 12 per cent of the fuel leaves the furnace unburned, the total loss is approximately 20 per cent. In other words, the combustion efficiency, as entirely distinct from furnace efficiency, is only 80 per cent.

This statement is typical, rather than an exaggeration, of furnace conditions which are common, but which are being remedied so far as operating conditions will permit by intelligent combustion engineering. It is doubtful, though, if for many years it will be possible to attain in industrial furnace practice a general average combustion efficiency, again as distinct from furnace efficiency, of more than 85 per cent.

This direct fuel loss is not, however, the only ill effect of incomplete combustion or of excess air. Both tend to materially depress the flame temperature. The amount of this depression can readily be calculated. In the case cited, with an excess of air of 25 per cent and 12 per cent of the carbon in the fuel leaving the furnace unburned, the calculated depression in the flame temperature of oil is 800 deg. fahr. Recent experiments prove that the actual depression is considerably greater than the calculated, and in the condition named, the true drop in flame temperature would probably be 1300 deg. fahr.

The rate of heat transfer between a heating medium and a body to be heated is proportional to the difference in the fourth power of the respective temperatures by radiation, and to the direct difference in the respective temperatures by convection. It will be obvious, therefore, that any depression of flame temperature must affect the potential production of the furnace. This is particularly true in the case of the lean fuels, to which there is a marked trend in the steel industry today.

Recuperation not only effects a definite fuel saving, but it permits combustion with the minimum excess or deficiency of air which practical conditions demand. It also assures greatly increased furnace production when the richer fuels are necessarily burned with a heavy deficiency of air or when very lean fuels are employed.

Heat Loss From Industrial Furnaces in the Flue Gases

If all the heat in the fuel were to be utilized in useful work and radiation in a furnace, the gases would leave at atmospheric temperature. This is obviously impossible in industrial furnace practice, and every degree of temperature above atmospheric represents a readily calculated fuel waste. The magnitude of this waste may be a little surprising to those who look askance at an over-all boiler efficiency of less than 85 per cent.

If we assume that it is possible to attain the theoretical flame temperature of 3900 deg. fahr., in an industrial furnace, and if we ignore the variation in the specific heat of the flue gases with temperature, it will be evident that the heat lost in the flue gases alone would be, approximately, the ratio of the temperature of the flue gases to the flame temperature. For instance, if the gases leave the furnace at 2400 deg. fahr., the waste is 61.5 per cent; if at 1500 deg. fahr., 38.5 per cent; and if at 1000 deg. fahr., 25.6 per cent.

if the waste gases can be utilized to preheat the combustion air to any degree, less of the heat in fuel will be required to raise the air to flame temperature and a definite saving must result. This is the function of a recuperator.

Curve 2, Fig. 1, shows the heat in the air required for the theoretical combustion of the richer fuels as a percentage of the total heat in the fuel. For example, the heat in the air required for the theoretical combustion of coke-oven gas is at 1000 deg. fahr., 17.5 per cent of the total heat in the fuel.

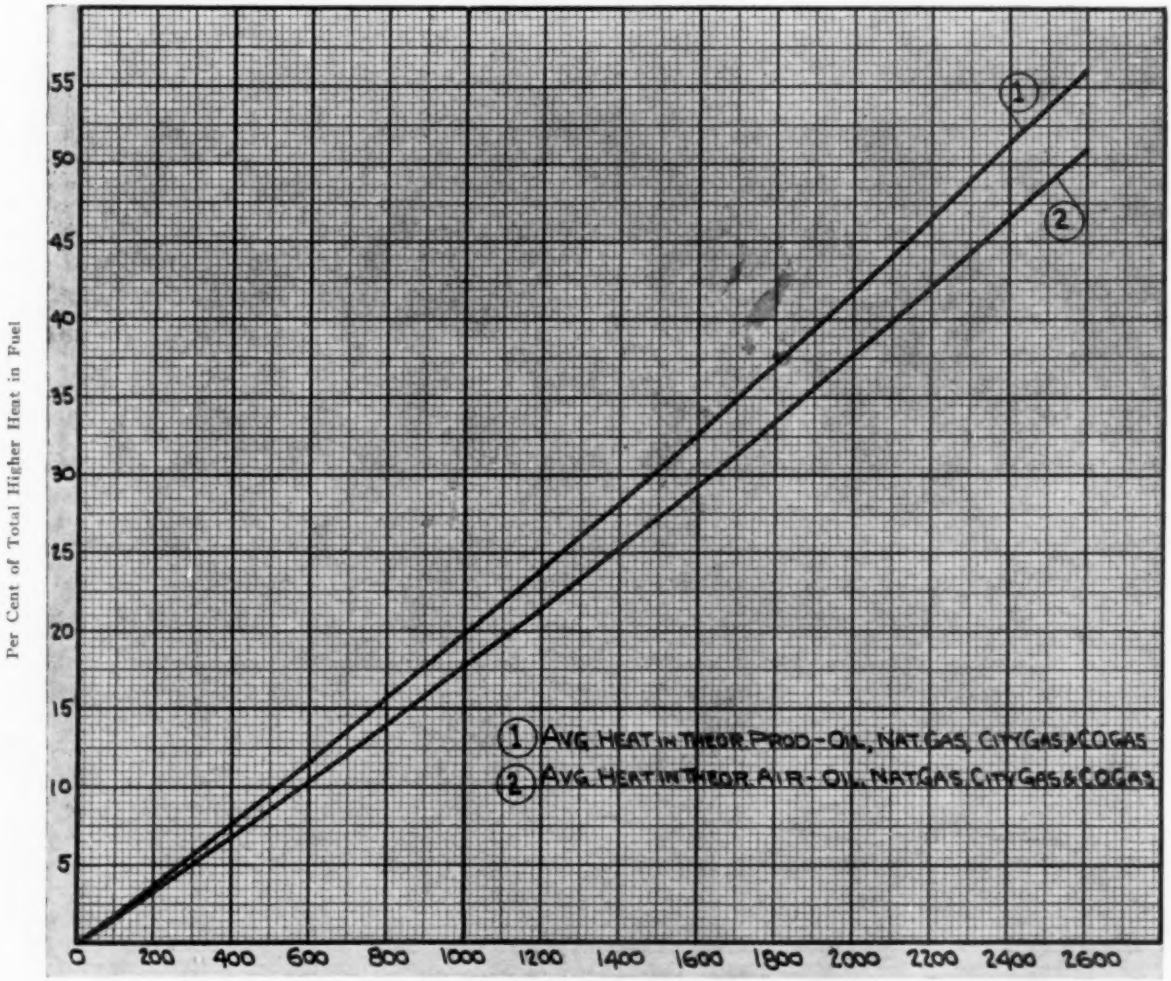

FIG. 1 HEAT CONTENT AS PER CENT HIGHER HEATING VALUE OF FUEL

The actual heat loss in the flue gases, assuming theoretical combustion, is shown as a percentage of the total heat in the fuel for the richer fuels (oil, coal, natural gas, city gas, and coke oven gas) in curve 1, Fig. 1.

The list of typical furnaces, Table 1, shows the extent of this waste.

It should again be emphasized that the losses shown are solely those due to the sensible heat in the flue gases, assuming theoretical combustion.

How Much Will a Recuperator Save?

It has been pointed out that in burning any fuel it is necessary to raise the combustion air to the flame temperature and that much of the calculated heat in the fuel is used in raising the combustion air to the flame temperature. It is equally obvious that

It would seem, therefore, that if the waste gases are utilized to preheat the air to 1000 deg. fahr. for a coke-oven gas-fired furnace, 17.5 per cent of the heat in the fuel would be returned to the furnace and the gas consumption would be reduced by that amount. Actually, however, the saving effected is considerably greater than this and increases both with the temperature of the waste gases and the inefficiency of combustion.

As an example, let us apply a recuperator to a continuous reheating furnace fired with any of the rich fuels. The exit-gas temperature is approximately 1800 deg. fahr., and the air is preheated to 900 deg. fahr. Again assume that it is possible to effect combustion with theoretical air, and ignore the loss due to the latent heat of water vapor, caused by the combustion of the hydrogen in the fuel. It is obvious that when the gases have left the furnace they are no longer available for work of any kind in

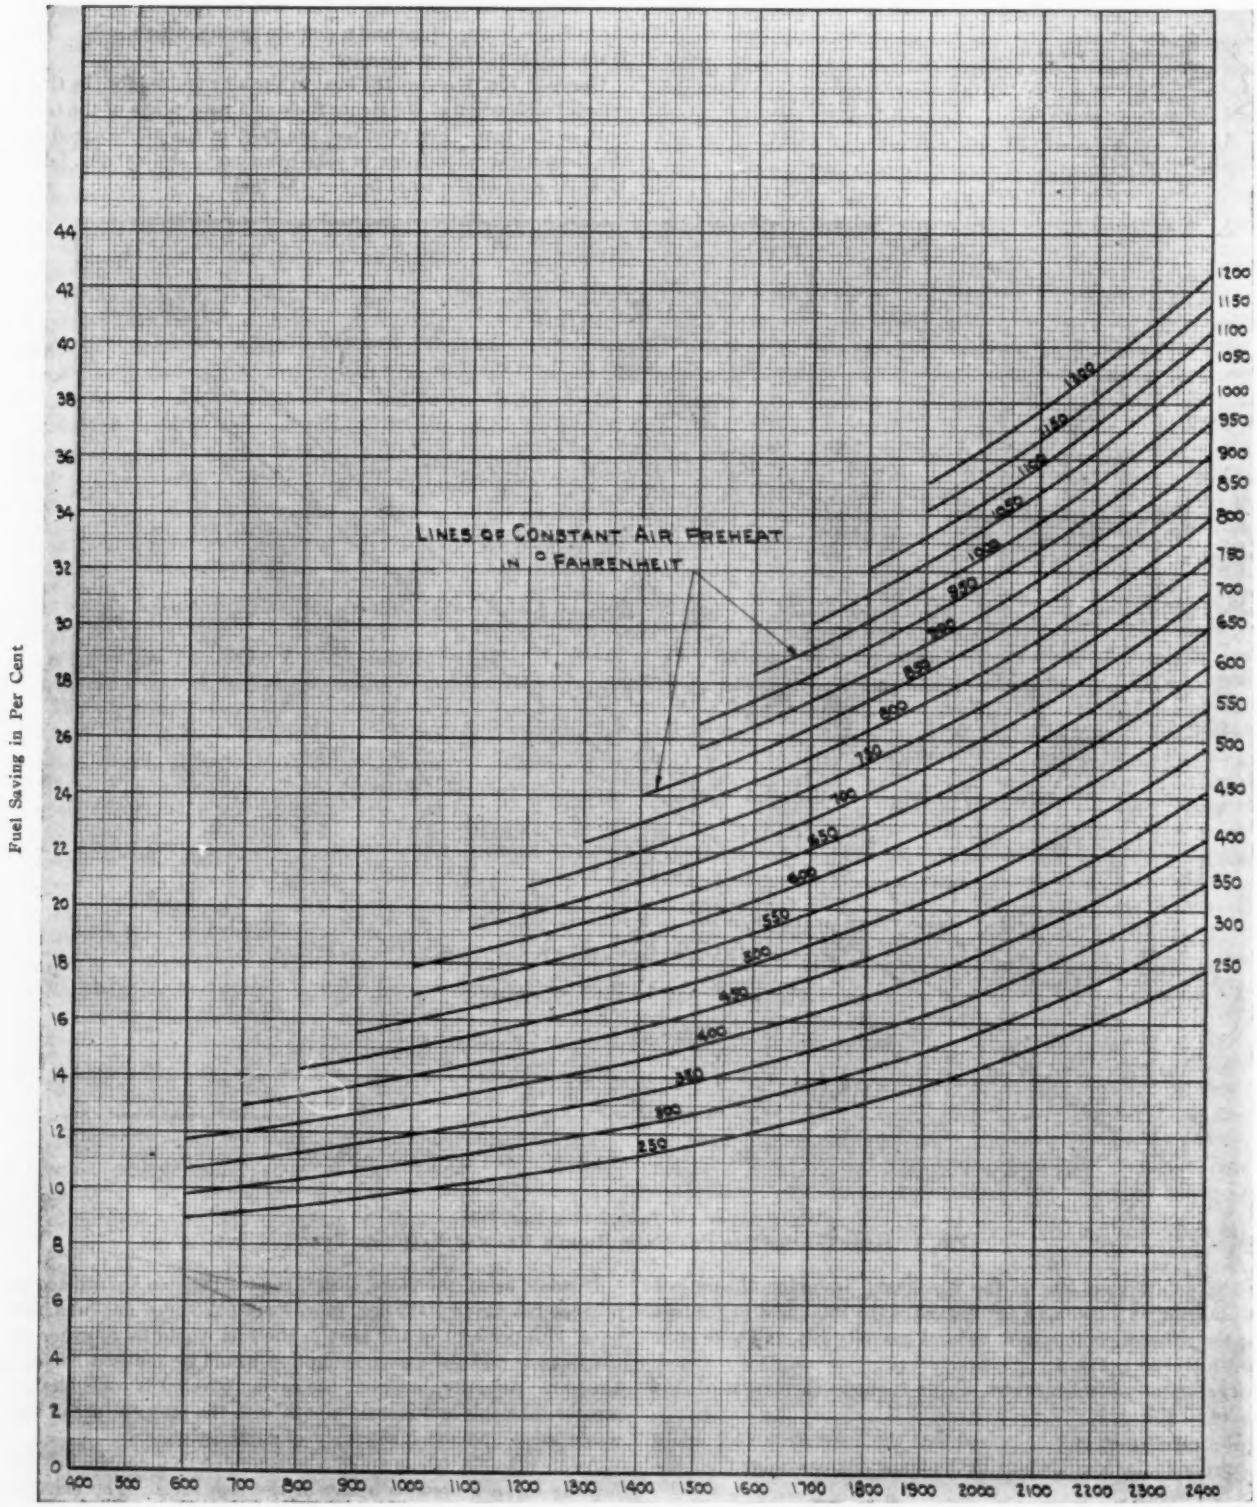

FIG. 2 PER CENT FUEL SAVING WITH VARIOUS WASTE-GAS TEMPERATURES AND AIR PREHEATS ABOVE 60 DEG. FAHR. FOR NATURAL GAS, OIL, COKE-OVEN GAS, AND CITY GAS

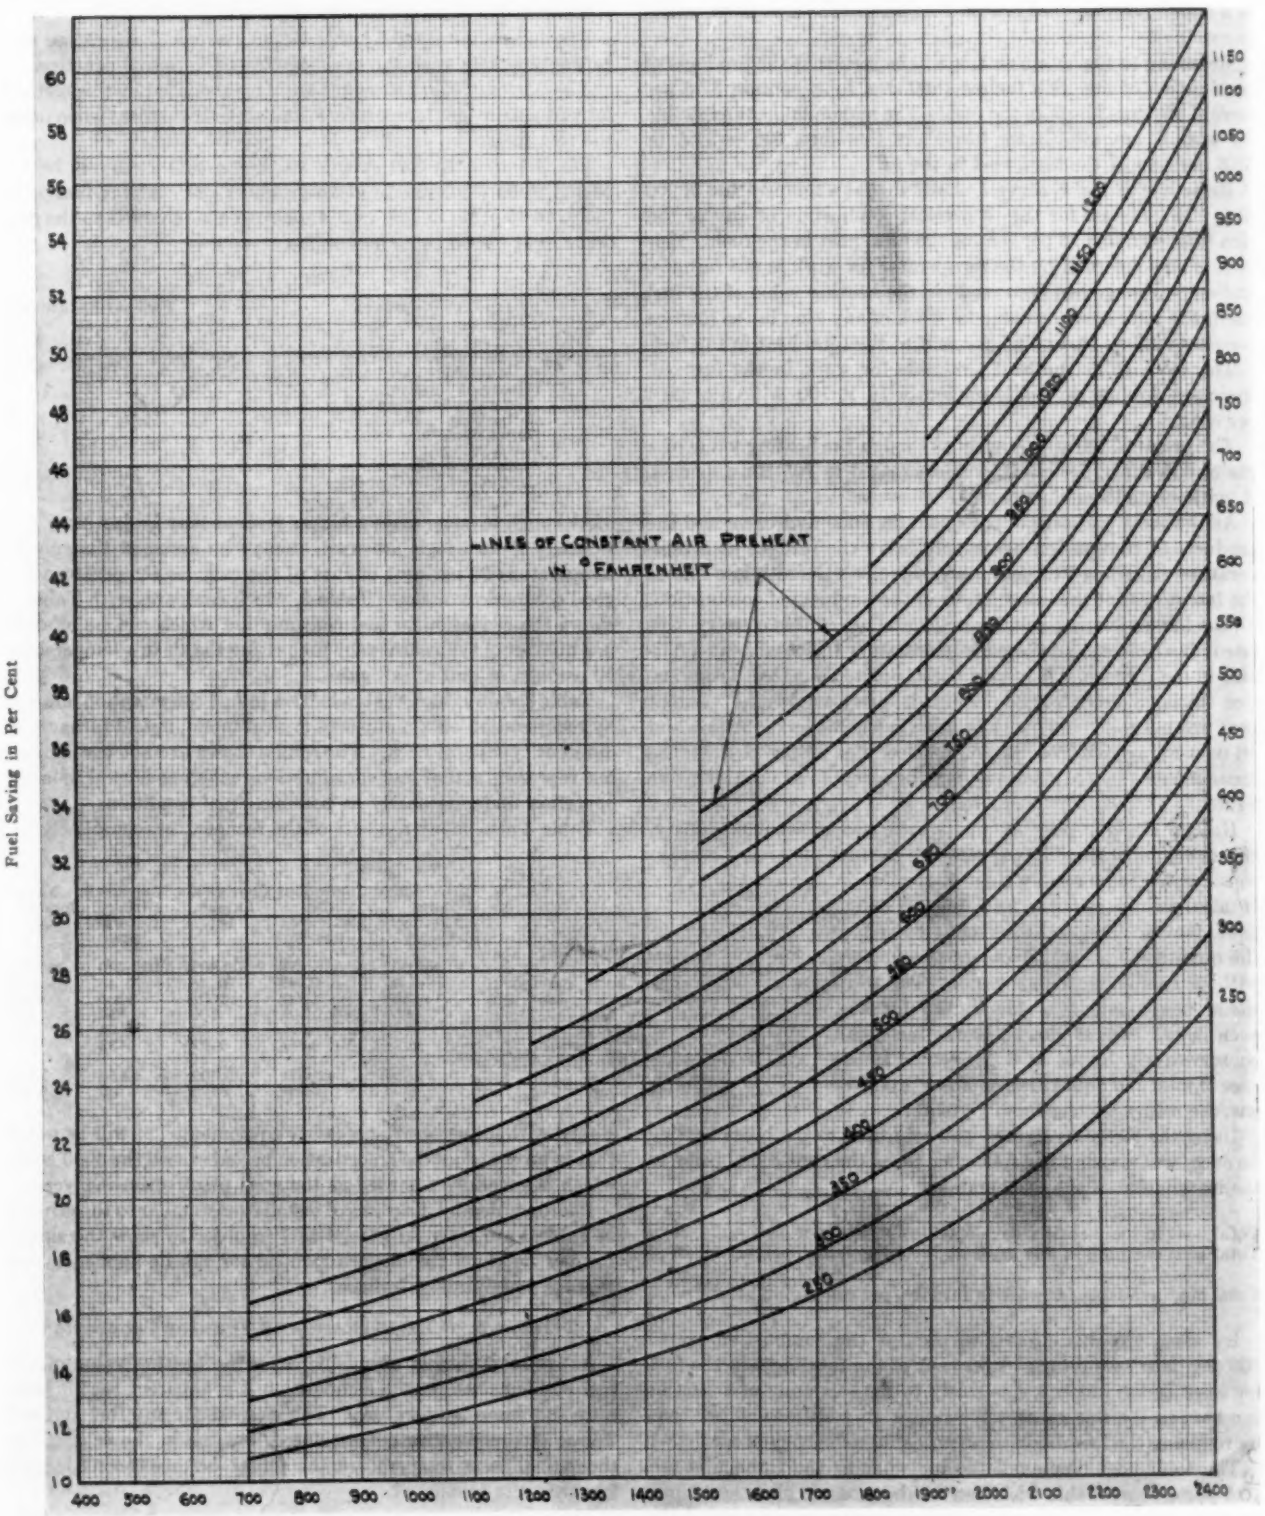

FIG. 3 PER CENT FUEL SAVING WITH VARIOUS WASTE-GAS TEMPERATURES AND AIR PREHEATS ABOVE 60 DEG. FAHR. FOR PRODUCER GAS

the furnace and that the heat available for work in the furnace is, as a maximum, the total heat in the fuel less the heat in the waste gases.

Referring to Fig. 1, curve 1, it will be seen that the products of combustion of any rich fuel at 1800 deg. fahr. contain 37.5 per cent of the total heat in the fuel. The maximum heat available for work of any kind in the furnace is, therefore, 100 — 37.5, or 62.5 per cent of the total heat in the fuel.

Reference to Fig. 1, curve 2, shows that at a temperature of 900 deg. fahr., the air for the theoretical combustion of any of the rich fuels contains 16 per cent of the total heat in the fuel. This heat is now returned by the recuperator for work in the furnace, and as no change has been made in the heating value of the fuel itself, the total heat available for work of any kind in the furnace becomes 62.5 + 16, or 78.5 per cent of the total heat in the fuel.

The increase in the heat available for work in the furnace, therefore the fuel saving, is obviously 16 × 100 ÷ 78.5 or 20.4 per cent.

The practical effect is exactly as though the heating value of a gas of 635 B.t.u. per cu. ft. were increased to 795 B.t.u. per cu. ft. without additional cost.

As the great majority of fuels contain some hydrogen, and the products of combustion necessarily leave the furnace at a temperature exceeding 212 deg. fahr., there is a definite loss due to the latent heat of the water vapor in the products of combustion. As the higher heating value is in general use in this country, this latent heat must be deduced in calculating the total heat available in the furnace. It has also been pointed out that a combustion efficiency exceeding 85 per cent is rarely attainable. Latent heat was not taken into consideration in the earlier discussion and an over-all average combustion efficiency of 85 per cent, still as distinct from furnace efficiency, may be accepted as a conservative figure.

Heated air, due possibly to its increased molecular activity, effects combination of its oxygen with the fuel considerably more readily than does cold air. It also plainly requires less time to attain flame temperature, and thus tends to reduce the quantity of air which enters the furnace without combining with the fuel. The additional heat made available in the furnace, even in the case of clean gaseous fuels, can conservatively be set at 3 per cent. In the case of solid and liquid fuels or of raw producer gas, the return is considerably greater.

Using the foregoing figures, and returning to the billet heating furnace, we now find the following to be the conditions prior to the installation of the recuperator:

Total heat in fuel actually developed in furnace, per cent	85.0
Total heat escaping in flue gases at 1800 deg. fahr., per cent.	37.5
Total heat available for work in furnace, per cent	47.5

By using the waste gases to preheat the combustion air to 900 deg. fahr., we return 16 per cent of the total heat in the fuel for work in the furnace, due solely to the salvaging of a part of the heat in the flue gases. We return an additional 3 per cent by reducing the losses due to an excess or deficiency of air.

The total heat now available for work in the furnace is the 47.5 per cent available with cold combustion air plus the 19 per cent due to the use of preheated air, and the total heat available with the recuperator becomes 66.5 per cent of the total heat in the fuel.

The increase in the available heat, therefore the fuel saving, is 19 × 100 ÷ 66.5, or 28.6 per cent, and the practical result is again as though a gas with a heating value of 475 B.t.u. per cu. ft. were increased to a heating value of 665 B.t.u. without additional cost.

The figures obtained by this method of calculation agree surprisingly closely with the savings effected in actual practice.

The curves in Fig. 2 show the savings calculated by this method for various exit-gas temperatures and air temperatures when using the rich fuels.

Fig. 3 shows the fuel saving which can conservatively be expected when using raw or clean producer gas. The reduction in fuel consumption in this case applies to coal charged to the producer, and not to cubic feet of gas.

Although in some cases a higher preheat may be justified, particularly if lean fuels are used, it may be assumed that an air temperature 50 per cent of that of the exit gas temperature is a good economic average. Table 2, which compares with Table 1, shows the reduction in fuel consumption which can be effected in a number of typical cases by preheating the air to a temperature 50 per cent of that of exit gases.

Table 3 shows the actual reduction in fuel consumption effected by recuperation on a number of typical metallurgical furnaces of different types and sizes. The results shown are not test figures, but represent actual fuel consumptions covering several months' operation under as nearly as possible equal conditions.

Table 3 also shows the cost of the recuperator, completely installed with all necessary accessory equipment. It will be noted that in no case does the amortization period exceed the 6000 hours which is generally regarded as the steel plant operating year.

TABLE 3

Type of furnace	Continuous billet	Continuous billet	Continuous forging	Galvanizing	Batch-type forging
Fuel	Producer gas	Coke-oven gas	Oil	Natural gas	Oil
Fuel consumption, B.t.u. per hour without recuperator	40,000,000	50,000,000	7,200,000	3,000,000	1,750,000
Fuel cost per million B.t.u., dollars	0.20	0.30	0.45	0.45	0.38

Saving, per cent	32	26	30	24	37
Value saving per hour, dollars	2.56	3.90	0.97	0.32	0.25
Cost of recuperator, installed complete with accessories, dollars	11,800	12,400	3,300	1,650	1,150
Amortization period, hours	4600	3180	3400	5150	4600

Photographs and diagrams of installations similar to those listed in Table 3 are given in Figs. 4 to 7 in order to show the simple manner in which the modern recuperator can be applied to the average metallurgical furnace.

Influence of Recuperation on Furnace Production

As recuperation, in effect, increases the heating value of the fuel without changing its composition it is apparent that it must raise the flame temperature. The increase for any fuel and any degree of preheat can be calculated, but, as in the case of the theoretical flame temperature, the actual increase is considerably less than the calculated.

The rise varies somewhat with the fuel and with furnace conditions, but tests under operating conditions indicate an increase in flame temperature of approximately 30 deg. fahr. for each 100 deg. of preheat.

The rate of heating in a furnace is of course a function of the difference in temperature between the heating gases and the

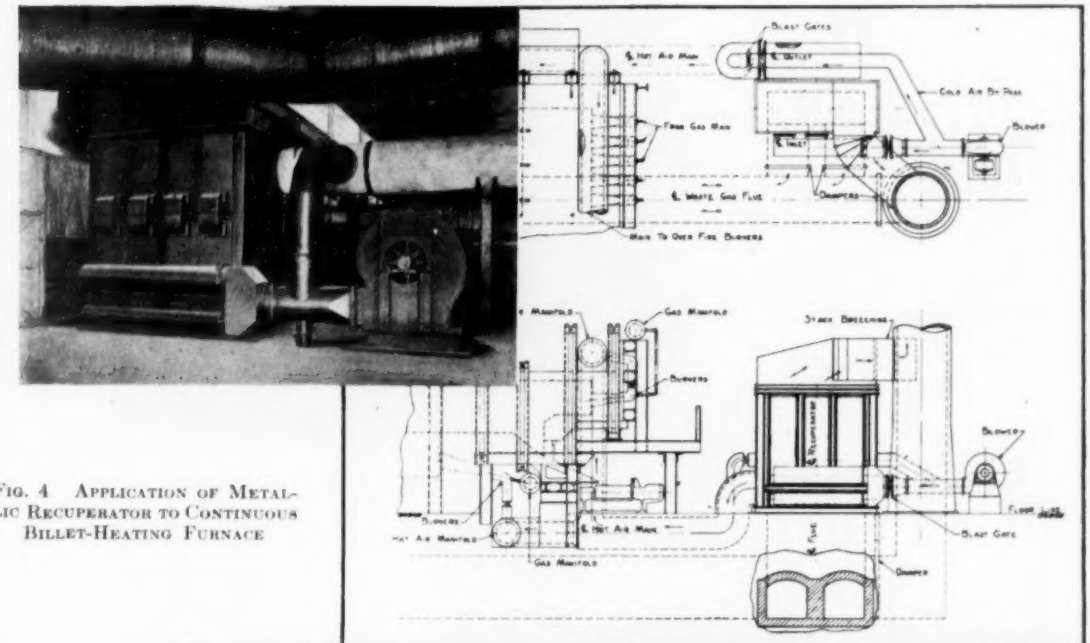

FIG. 4 APPLICATION OF METALLIC RECUPERATOR TO CONTINUOUS BILLET-HEATING FURNACE

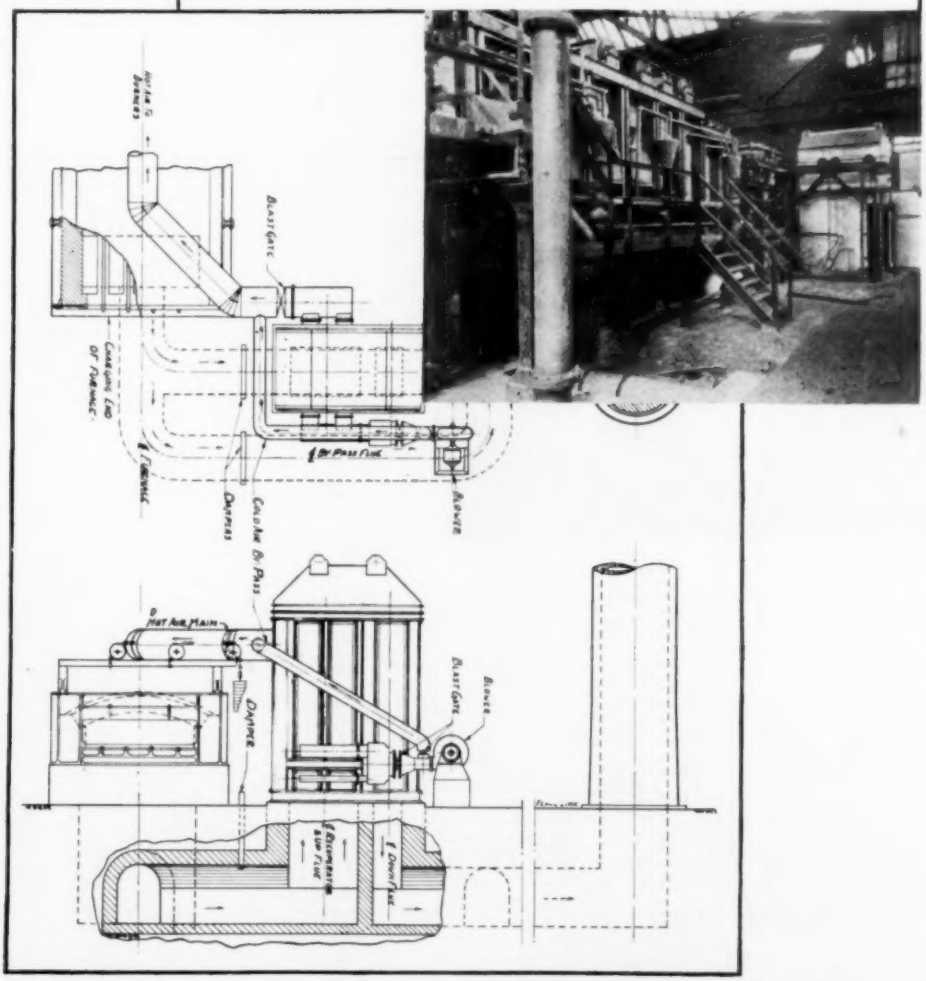

FIG. 5 ANOTHER METHOD OF APPLICATION IN BILLET-HEATING FURNACE

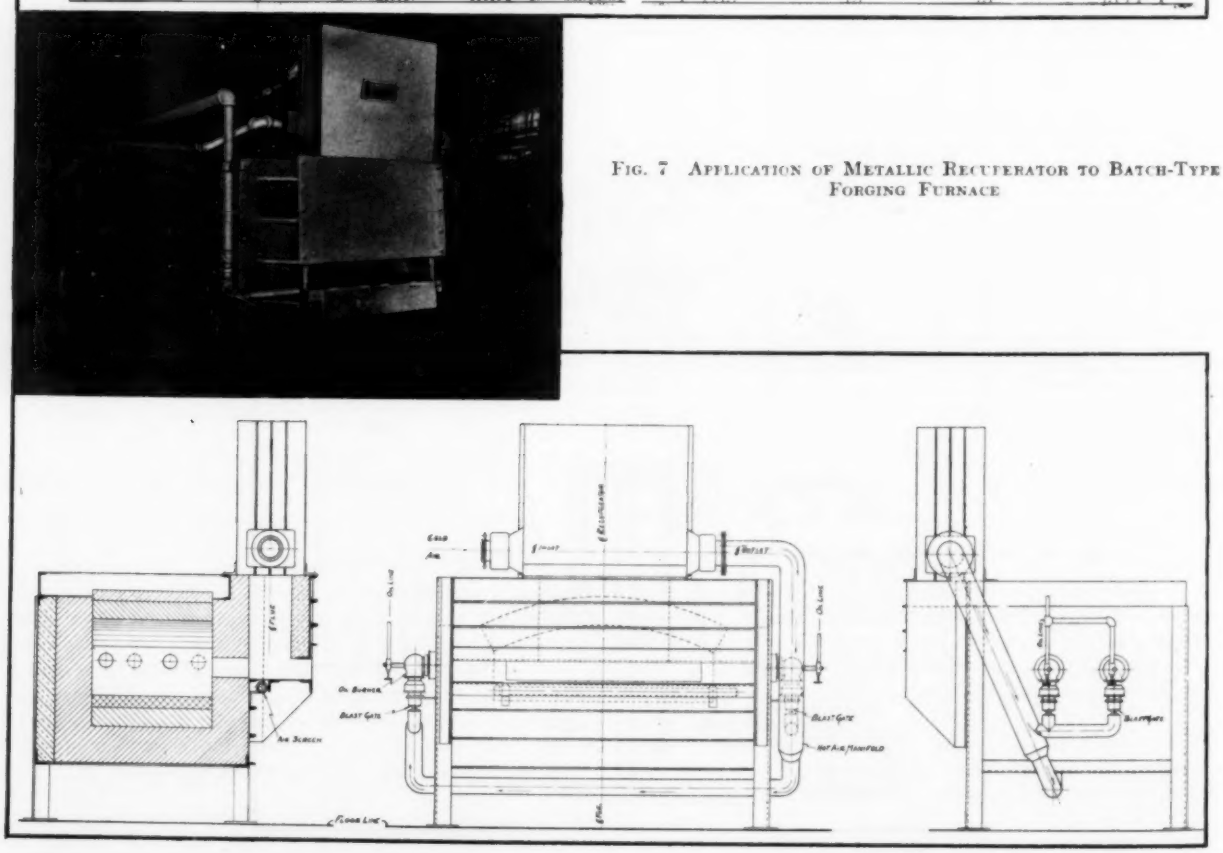

FIG. 7 APPLICATION OF METALLIC RECUPERATOR TO BATCH-TYPE FORGING FURNACE

material to be heated. When, therefore, it is possible to utilize a furnace temperature higher than that attainable with cold combustion air, a recuperator will effect a marked increase in the possible production.

With the rich fuels the increase in production can only be utilized when the material heated in the furnace is to be raised to a final temperature exceeding 2000 deg. fahr. With lean fuels, such as clean cold producer gas, low heating value mixed gases or straight blast-furnace gas, it is often difficult to obtain the flame temperature required for the higher temperature operations, and recuperation or regeneration becomes a necessity. A marked increase in production is often to be observed when these fuels are used in connection with the lower temperature operations.

If it is necessary to carry a furnace temperature exceeding 2400 deg. fahr., using either rich or lean fuels, recuperation will effect an increase in production of as much as 40 per cent.

The reduction in fuel consumption due to recuperation is also a factor in increasing the potential production of a furnace. The furnace volume in many cases limits the quantity of fuel which can effectively be burned in a furnace and, therefore, also limits the production. As recuperation increases the effective fuel capacity of a furnace it also increases the potential production.

There is a more or less general impression that the increase in flame temperature inherent to recuperation is disadvantageous in furnaces operating at temperatures below 2000 deg. fahr. There is not necessarily, however, any direct relation between flame temperature and furnace temperature. A high-temperature flame can be diffused as a comparatively low temperature atmosphere in the furnace by intelligent use of the radiated heat from walls, arch and hearth, or by recirculating the gases through the flame. The addition of a recuperator simply means that less fuel is required to maintain a given furnace temperature for a given production.

Some outstanding examples of the successful application of recuperation are in connection with such low-temperature operations as copper-strip annealing and galvanizing pots.

Use of Preheated Air in Connection With Lean Fuels

The increased production of blast-furnace gas and its more efficient application have provided many steel plants with a surplus of this fuel, and there is a rapidly increasing tendency to use this gas in connection with the higher temperature operations, such as heating furnaces and soaking pits.

The theoretical flame temperature of the average blast-furnace gas is only 2500 deg. fahr., and as it is not possible to develop more than 80 per cent of this, the maximum flame temperature attainable with cold combustion air will scarcely exceed 2000 deg. fahr. The actual flame temperature required in heating furnaces and soaking pits may be as high as 2700 deg. fahr., and it is evident that the effective heating value of the blast-furnace gas must be materially increased before it can be utilized. This is done by enriching the gas with another of higher heating value, by preheating the air, by preheating the gas, or by preheating both air and gas.

To attain a flame temperature of 2700 deg. fahr., it is desirable that the theoretical air-gas mixture have an effective heating value of 75 B.t.u. per cu. ft., as compared with 57 B.t.u. per cu. ft. of mixture when using cold air and blast-furnace gas.

If coke-oven gas is the enriching medium and the mixed fuel is to be burned with cold air, it is necessary to add 40 parts by volume of coke-oven gas, with a net heating value of 440 B.t.u. per cu. ft., to 60 parts of a blast-furnace gas, with a net heating value of 97.5 B.t.u. per cu. ft. The heating value of the mixed gas is 234.5 B.t.u. per cu. ft. and the heating value of the theoretical cold air-gas mixture is 75 B.t.u. per cu. ft.

By using a recuperator to preheat the combustion air to 1000 deg. fahr., the required 75 B.t.u. per cu. ft. of air-gas mixture can be obtained by using only 12.5 parts of coke-oven gas to 87.5 parts of blast-furnace gas—a reduction of nearly 70 per cent in the quantity of coke-oven gas and an attendant improvement in combustion and furnace atmosphere. This mixed gas has a net heating value of 140 B.t.u. per cu. ft. and requires 1.16 cu. ft. of air for the theoretical combustion of 1 cu. ft. This air when raised to 1000 deg. fahr. contains approximately 22 B.t.u., raising the effective net heating value of the mixed gas to 162 B.t.u. per cu. ft. and giving a heating value for the air-gas mixture of 75 B.t.u. per cu. ft.

An interesting installation of recuperators is planned in a large steel plant in the Chicago district. In this case it is proposed to use straight blast-furnace gas to raise steel to 2400 deg. fahr. in large continuous billet-heating furnaces. Both air and gas are to be heated to 1000 deg. fahr. in special metallic recuperators.

Assuming a gas with a net heating value of 97.5 B.t.u., weighing 0.08204 lb. per cu. ft. wet and requiring 0.05566 lb. of air for the theoretical combustion of 1 cu. ft. of gas, the heat in the air at 1000 deg. fahr. is approximately 13 B.t.u., and the heat in the gas approximately 20 B.t.u., making the total effective heating value 130 B.t.u. per cu. ft. The heating value of the air-gas mixture is here again 75 B.t.u. per cu. ft.

Conclusion

It has been the prime object of this paper to effect a realization of the value to industry of recuperation. For this reason, any description of the highly developed types of commercial equipment now available has been omitted. The huge expenditures on fuel and its increasing value are rapidly making recuperation essential to the metallurgical industries. Even more essential, therefore, is a wider appreciation of its advantages.

Discussion

Max Sklovsky.[2] The author has made a substantial contribution on the subject of economies of fuel in industrial furnaces through the process of recuperation. The data are conservative, and his claims are frank and modest.

Comments made on this paper show that there has been considerable disappointment in the results obtained from recuperators. The writer does not believe that the disappointments in a number of cases offset the actual merit obtained from recuperation; therefore, as a user of recuperators, he desires to indicate the following:

1 The writer has used recuperators regularly for 11 years on a large number and a large variety of furnaces, and nearly all of these are still in use, and in most cases the original recuperators are still serving, although the earlier recuperators were not a type to insure the lasting qualities with which some of the present types are made.

2 The failure of recuperation is frequently attributed to lack of cooperation on the part of users. The abuse to which furnace equipment is put is inexcusable.

3 The purchaser of the recuperative equipment expects too much of such equipment. In many instances the furnace construction does not permit proper application of recuperators, and frequently the user is unwilling to modify the furnace construction for the purpose, thus forcing the recuperator agency to apply recuperation under conditions that are not at all favorable. The recuperator manufacturer under the present conditions is obliged to take on the burden which does not belong to him of a redesign of the furnace, and the responsibility is too readily accepted by the recuperator salesmen.

---

[2] Chief Engineer, Deere & Co., Moline, Ill. Mem. A.S.M.E.

4 The application of a recuperator properly carried out requires close observation of the particular furnace, an engineering analysis of same, and frequently supplying a partial redesign to permit the recuperator to be installed. It also requires follow-up observations, adjustments and engineering attention, all of which result in very high cost of application of recuperators; and with the recuperator manufacturer absorbing all of the contingent expenses and responsibility for the results, the installation price is frequently excessive. A little attention and cooperation on the part of the purchaser will materially reduce the cost and improve the results of recuperation. Without such cooperation, fewer successes will be attainable.

5 The results of recuperation are numerous, among which can be listed reduced fuel consumption, higher temperatures, more rapid heating, simpler control, and greater output.

E. W. Wagenseil.[3] The author deserves thanks for the clear and logical manner in which he has covered the subject. The paper points the way to definite results in the way of lowered heating costs, increased tonnage, and higher quality heating, and it should create a wide interest among steel-plant engineers and mill-operating officials.

There are one or two things which might perhaps be somewhat misleading, and which should have some further discussion. The writer would like to call attention to the fact that the temperature to which air can be preheated is by no means limited to 50 per cent of the waste-gas temperature, which the author mentions as being "a good economic average." The curves which he shows in Figs. 2 and 3 show air temperatures up to about 65 per cent of the waste-gas temperature. We have several installations of Blaw-Knox preheaters in connection with continuous furnaces where the air is heated to as high as 75 or 80 per cent of the waste-gas temperature. This high preheat is particularly desirable in furnaces where cold billets are charged and the waste-gas temperature leaving the furnace ranges from 1400 deg. fahr. to as low as, perhaps, 1000 deg. fahr. In such cases it is desirable to heat the air to as high a percentage of the waste-gas temperature as possible.

It should be pointed out, however, that in order to utilize high air temperature successfully it is necessary that the burners and the furnace be properly designed for the use of high air preheat; otherwise burned steel and serious cinder conditions may be the result.

It has occasionally happened in the past that cases of this kind have been offered as proof that high air preheat cannot be used advantageously on steel-heating furnaces. Actually such cases merely demonstrated that the burners and furnace were not properly designed for the amount of preheat being used. Mr. W. P. Chandler, Jr., in his article on "Economical Combustion," in the June issue of *Iron and Steel Engineer*, points out some of the factors which have a vital bearing on the subject of proper burner design for high air temperatures.

The author mentions that metallic recuperators are in successful operation on furnaces with waste-gas temperatures as high as 2600 deg. fahr. The writer is sure that this statement was not intentionally meant to be misleading and that the author does not claim that there are metallic recuperators in service where the temperature of the waste gases actually entering the recuperators is anything like 2600 deg. fahr. In cases of this kind it is absolutely essential that the waste-gas temperature should be brought down to something like 1800 deg. fahr. in order not to subject the preheater at times to temperatures which might be destructive to the materials of which it is made.

It is unsafe to try to accomplish this by admitting cold air to the waste-gas flue as the waste gas frequently contains fairly high percentages of CO, and in such gases the admission of cold air will at once start secondary combustion in the preheater, with disastrous results. The ideal way to reduce high waste-gas temperature is by dilution with some of the same gases which have been through the preheater and are at a comparatively low temperature. This can only be done, however, if a waste-gas exhaust fan is used in connection with the preheater.

There are a considerable number of Blaw-Knox regenerative air preheaters in service on one-way fired soaking pits where the waste-gas temperature leaving the pits when the ingots are up to rolling temperature sometimes reaches 2400 deg. fahr. or higher. We reduce this temperature to a maximum of 1800 deg. fahr. entering the preheater by means of a thermostatic control (the arrangement of which is located in the hot waste-gas intake to the preheater), which automatically takes part of the cooled waste gas which has been through the preheater and exhaust fan and mixes this cooled gas with the hot waste gas from the pits, bringing the temperature down to 1800 deg. entering the preheater. This method makes it possible to operate the preheater with safety in connection with all types of heating furnaces no matter how high the temperature of the waste gas leaving the furnace.

Harold F. Wood.[4] American industry has reached a point in its development where costs of every detail operation must be watched with the utmost care and the maximum of efficiency be obtained if profitable operation is to be secured.

In the metal-working industry the question of furnaces is a very considerable item of plant equipment, and the question of furnace efficiency is a very important consideration in product cost. It is no longer sufficient merely to install a piece of heating equipment that will heat metal for a certain operation uniformly and of a certain volume, but it is necessary to give detail study to the question of the most economical fuel to use and the burning of that fuel in the most economical way.

Recuperation is a perfectly logical way of reducing fuel cost. The author has pointed out clearly how this can be done. The tables presented are correct and represent in each case exactly what the possibilities for heat salvage are. From a practical standpoint it is not, however, always possible to realize the savings shown in the tables. This is due to two reasons. In the first place, in continuous furnace operations, where the flow of material through the furnace is on a definite time cycle, equilibrium conditions of the gases are upset considerably by the frequent opening and closing of the doors, making it impossible to get all the waste gases through the recuperator. This is very noticeable in low-temperature furnaces used at temperatures around 1000 to 1200 deg. fahr. In the second place it is necessary to use cold air for atomization, and the volume of cold air runs, in the majority of cases, with present available burner equipment, approximately 25 per cent of total air. This of course reduces possible economies. It is hoped that serious thought will be put on the subject of burners for use with preheated air with the hope of developing one that requires little or no cold air for its operation. It is also hoped that the furnace engineers will be able to design their furnaces so as to assure maximum amount of waste gases passing through recuperator.

The metallic recuperator as a unit is very good. The writer cannot agree entirely with the thought of using metallic recuperators on waste gases entering the recuperator at temperatures of over 2000 deg. fahr. He has been very much interested in recuperators since the first ones were built and will say that he

[3] Sales Engineer, Blaw-Knox Co., Pittsburgh, Pa. Mem. A.S.M.E.

[4] Chief Metallurgist, Ingalls-Shepard Division, Wyman-Gordon Co., Harvey, Ill.

has had no thought of installing a furnace in the past eight years without recuperation. We have twelve continuous billet furnaces operating at forging temperatures and seven large continuous heat-treating furnaces all equipped with metallic recuperators. Although we have had some recuperator trouble, this trouble has been the least per dollar returned on investment of any equipment in the plant, and any furnace installation made by our company in the future will include recuperation.

IS-52-10

Design and Construction of Hot Saws for Cutting Heavy Sections

By A. B. PEARSON,[1] MUNHALL, PA.

Sawing is an ancient art and it may be said without fear of contradiction that its origin dates from primeval times. A stone or a shell with a ragged edge may have served as the implement, and the pressure or feed, as well as the speed, were then, as now, very important factors in the undertaking. Other methods of cutting have been found, but the abrasion process is still the one that is most generally employed for cutting heavy material to length. In the use of this process, as in sawing, the cutting tool is generally harder than the material being sawed. The author describes saws for cutting hot and cold metals and gives results of tests on a variety of saws.

IN THE sawing of metals such as steel there are two distinct fields, that of sawing steel cold and that of sawing steel hot. When sawing steel cold, the heat developed is not an aid to the cutting and must be kept within limits, whereas when sawing steel hot, the heat must be created at a rapid rate to insure successful cutting. In the method of sawing steel hot it is necessary to create this difference in temperature and consequent hardness between the cutting tool and the material being cut, and it is clear that without this difference in hardness no cutting could take place. Therefore in hot-sawing the rotating steel disk has two functions to perform (1) to heat the steel by friction, and (2) to remove at least a part of the steel so heated.

Some cooling agent has to be used to cool the saw blade for continued cutting. It is evident that the friction required is in inverse proportion to the temperature of the steel sawed. This method of cutting steel is used extensively in steel manufacturing plants and warehouses throughout the country.

In steel-mill practice the name "hot saw" is only applied to a sawing machine used for cutting red-hot steel coming directly from the mill. The name "cold saw" is applied to a similar machine used for cutting cold steel coming from the cooling bed or the stock pile. In both of these machines the cutting is done with a rotating saw blade or disk having a peripheral speed of several thousand feet per minute. The name "cold saw" as applied to this type of machine is a misnomer, for by cold saw ordinarily is meant a saw with a rotating disk having hardened teeth and which, with the aid of a cutting lubricant, rotates at a speed of approximately 100 ft. per min. Some writers to avoid this inconsistency, have given the cold saw, known as such in the steel mills, the name cutting-off machine, friction-sawing machine, fusion-disk machine, or simply "cold saw." Acknowledging the error the author will also use the name "cold saw."

In mill practice, a delay between the finishing mill and the hot saw may cause the steel to cool, making it necessary to use a saw blade for cutting cold steel on a saw that is normally used for hot sawing. This illustrates the relationship between the two saws, the principal difference being the cutting edge and the speed of the saw blade.

The introduction of the rolled shaped steel sections brought about the necessity of cutting without distortion and at a higher speed than had been done up to that time. Therefore the high-speed hot saw as well as the cold saw came into being. The Carnegie Phipps Company, Ltd., which later became the Carnegie Steel Company, has a record of installing a cold saw in the year of 1887. Two years later in 1889 the same company installed a hot saw for sawing hot steel.

The early high-speed hot saws used for cutting steel were of the stationary-frame type, having a manual-feed arrangement. For light work these saws have been and still are efficient, but as the material to be cut has increased in size, the manual feed had to give place to some sort of power feed. With the introduction of the power feed, a greater ease in the manipulation of the feed was accomplished. However, the power feed brought a less sensitive feed movement.

The stationary-frame type of saw makes it necessary to feed the material to the saw while cutting. This is satisfactory for short lengths, but for long lengths the material has to be clamped in position for each cut. The clamping caused delays in production and therefore a change became imperative. However, the disadvantage could not be easily overcome without a radical departure in the design of the saw.

Thus came into use the drop saw and the pendulum saw which allows the material to be stationary while the saw frame is moved relative to the material being cut. The drop saw, also called the balance saw, is fed from the top down; and the pendulum saw is fed from the side in a swinging fashion. The drop saw is now used for cutting rails and material of a similar character.

With the drive and the saw blade mounted on opposite ends of a walking beam, the drop saw is fed by tilting the walking beam so that the saw blade comes in contact with the material to be cut. For steel with a varied rectangular cross-section this saw is not suitable except for narrow widths.

The pendulum saw, although having the advantage of cutting from the side, has other features not conducive to good design. The two most outstanding are the high suspension and the vertical belt drive, the latter feature being perhaps the more objectionable. It should be said, however, where floor space is limited the pendulum type of saw may be justified. It was but natural that the saw development should take this course because of simplicity of design and the consequent low cost of production. As the structural material increased in size it became necessary to design a saw free from the limitations previously encountered.

[1] Engineer, Carnegie Steel Company. Mr. Pearson received his technical education in Sweden, and at 22 came to the United States. He studied nights at the Carnegie Institute of Technology. He was employed by the Pittsburgh & Lake Erie Railroad at the McKees Rocks Shops. When high-speed steel came into use, it was his lot to run tests on a variety of machine tools. He was employed by the H. K. Porter Locomotive Works as draftsman and designer of locomotives from 1907 to 1917. Since that time he has been with the Carnegie Steel Company at Homestead as engineer, principally on estimate and design of steel-mill equipment, rolling-mill machinery, and plants.

Presented at the Fourth National Iron and Steel Meeting, Chicago, Ill., Sept. 24 to 26, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

After trying and finding use for the stationary saw, the tilting, and the swinging saw one comes to the sliding saw. The stationary and the sliding-frame saw does the sawing from the side in the same manner except that the material being cut is moved in a stationary saw and remains stationary in a sliding saw.

The sliding-frame saw has met with success particularly when used for the cutting of heavy structural-steel sections. There may be a number of details that can be improved or altered to suit different conditions, but the design of the sliding frame moving horizontally on a stationary base is a basic principle in design that will remain.

The Sliding Frame Saw

The so-called sliding frame is really a rolling frame for the larger saws because the frame rolls on a stationary base plate.

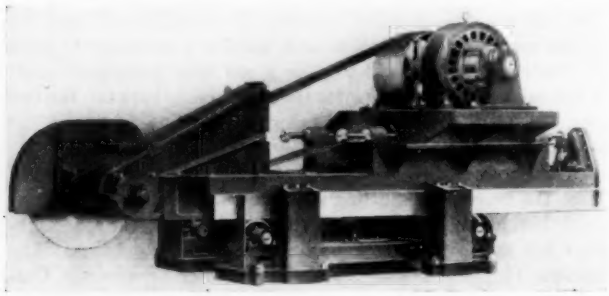

Fig. 1 Belt-Driven Sliding-Frame Saw

The belt-driven saw (Fig. 1) of this type has a motor mounted on the frame with a belt from the drive pulley to the saw arbor. The saw blade is mounted on one end of the arbor shaft which permits a rapid change of saw blades; however, a heavy construction is required as the load is overhung and one sided. The horizontal travel of the saw frame is ordinarily about 6 ft. for saws now used for cutting the heavier structural beams. With this travel it is evident that the saw frame must be long and also heavy, not only for strength, but also to balance the loads when the saw frame is in one of the two extreme positions. The saw frame must be heavy to absorb the minute rapid vibrations set up by the rotation of the saw blade.

Saws of this type have advantages, the most important being that the saw frame is outside and adjacent to the table on which the material is moved to sawing position. This permits a ready means for the disposal of crop ends and scrap into a pit located immediately under the table. In mill practice this is a very important factor where several thousand tons have to be sawed in a day's time. The sliding frame lends itself equally well for sawing either hot or cold steel.

Another sliding frame saw (Fig. 2) has met with considerable success. The frame of this type of saw is built in a goose-necked fashion, the lower part extending under the table which supports the material as it is being cut. The saw-drive motor is mounted directly on the saw arbor, thus eliminating the belt. This saw has so far been used only for sawing cold material, but with means for cooling the motor, there seems to be no reason why the direct drive cannot be applied to a saw for sawing hot steel. It can readily be seen that the direct drive has potentialities which if realized would in time eliminate the belt-driven type. However, this has not been done, and it seems that the difficulty is in the main an electric problem.

The Saw Feed

In general the larger hot saws are equipped with hand-controlled power feed having a hydraulic or hydro-pneumatic, and in later years, an entire electric arrangement. The feed is arranged so that the movement is variable in speed when the saw blade is making the cutting stroke and either variable or constant in speed on the return stroke.

In the hydraulic-feed arrangement the liquid is forced by a pump to the feed cylinder. A spring-actuated relief valve and choke are placed in the pipe line between the operating valve and the cylinder to limit the pressure and the flow respectively. A fast return stroke is secured with bypassing the liquid through a one-way check valve. An air cushion is sometimes used as a shock absorber when the feed cylinder is connected to a hydraulic accumulator system. The rate of feed is dependent on the opening of a valve and in practice is not as flexible as a geared motor-driven feed system. There may be some objection to possible leakage at cylinder packing and by freezing, but in the main this feed is simple and perhaps less costly than any other power feed.

The electrical power feeds are principally of two kinds, namely, what may be called the direct and the indirect types. The direct electrical feed has two motors running in opposite directions driving through an enclosed differential set of gearing. When the two motors run at the same speed there is no movement of drive shaft and no feed, but as the speed relation is altered the drive shaft rotates. This is analogous to the differential in an automobile with motors in place of the back wheels. Power is transmitted from the drive shaft to the saw frame through a geared pinion and rack. This feed admits an accuracy of control, but the disadvantage is that two continuous-running motors have to be used when one motor really does the work.

The indirect electrical type of feed is driven by one adjustable-

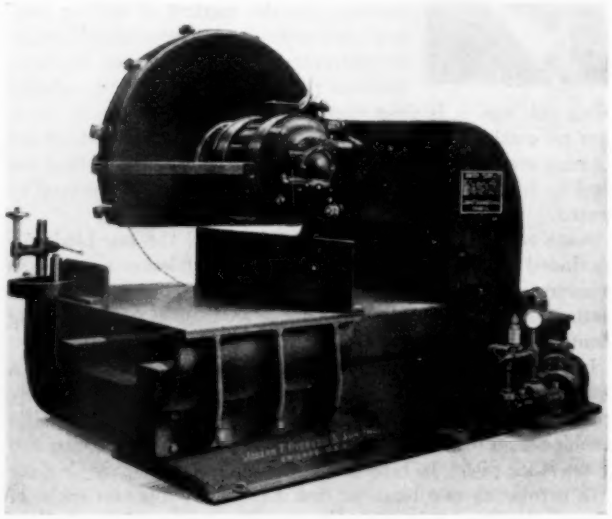

Fig. 2 Direct-Drive Saw With Goose-Neck Frame

speed motor through a set of spur reduction gears to a drive shaft. The current to drive this motor in the feed direction is obtained from a generator coupled directly to the saw-motor drive shaft. However, when the feed motion is reversed the current comes from a separate mill circuit. Thus a variable voltage is used in the cutting direction and a constant voltage on the return stroke. An added safety factor is the tripping of an overload relay, that stops the feed by dynamic braking when the saw motor reaches a value near that at which the saw stalls. Generally, in motor-driven saws having power feed, an ammeter is used to indicate to the operator the rate of feed permissible without stalling the saw motor. As the feed is entirely hand controlled, the saw is therefore subjected to considerable abuse and at times to the very

limit of doing work. In the sawing of varied sections of heavy-shaped steel it is desirable to have considerable range in the speed of the feed movement. This range should be from 1 to 60 ft. per min. in feed direction, having the latter speed on the return stroke.

The Saw Drive

The belt-driven saw used for cutting the heavier Carnegie beam section as now rolled at the Homestead steel works requires a 300-hp. motor. A constant speed 220-volt induction motor is being used running at 720 r.p.m., having a belt pulley mounted on an extended motor shaft. The belt used is of canvas and endless, running at a speed of 7000 ft. per min.

The direct-driven saw used for similar, although lighter, service has a motor designed with a minimum outside diameter as the motor has to pass over the material being cut. The motor used

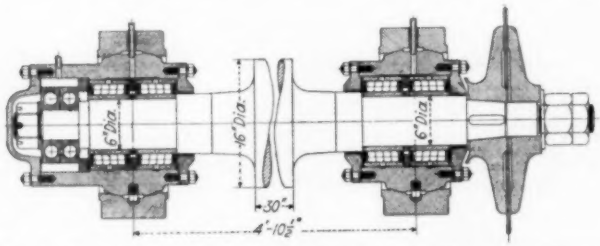

Fig. 3 Saw-Arbor Bearings Applied to a 300-Hp. Belt-Driven Saw

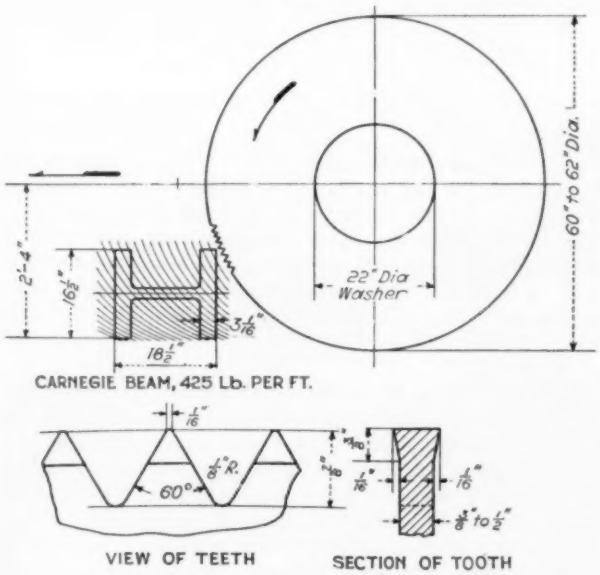

Fig. 4 Saw Blade for Cutting Hot Steel

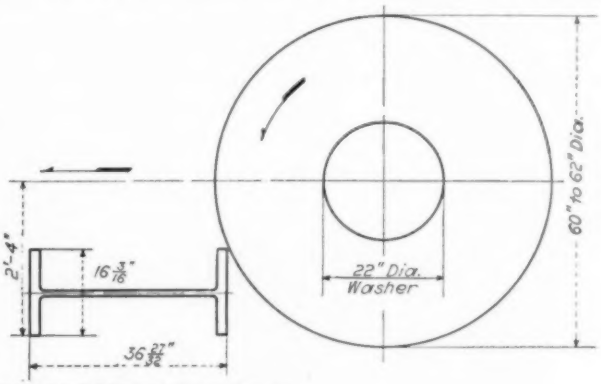
(Chemical composition: C = 0.30–0.36, Mn = 0.45–0.60, P = not over 0.04, S = not over 0.04, Si = 0.06–0.08. Heat treatment: Heated to 810 deg. cent., held ½ hr. and air cooled, then heated to 500 deg. cent., held ½ hr. and air cooled.)

for driving this type of saw is a specially designed 125-hp. induction motor, running at a speed of 1500 r.p.m.



The Saw Arbor

The saw-arbor bearings as applied to the belt-driven saw have gone through stages of trials and changes more than any other part of the saw. At a speed of approximately 1500 to 1800 r.p.m. and a comparatively heavy load, the ball and roller bearings have here found a ready application. This, however, has not been accomplished without some grief, more due to error of application than to any inherent fault of the bearings.

Fig. 3 shows a design which has been found satisfactory when applied to a belt-driven saw arbor. This design admits of linear expansion of saw arbor without binding of bearing races relative to the arbor. It is important that a separate thrust bearing be used for the heavier work.

The Saw Blade

The saw blade is to the operating man the most important part of a saw. Because of rapid wear and replacement it is a source of high upkeep cost. In giving type and size of saw blades

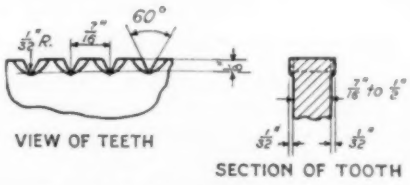


Fig. 5 Saw Blade for Cutting Cold Steel

(Chemical composition: C = 0.24–0.30, Mn = 0.40–0.50, P = not over 0.04, S = not over 0.04, Si = 0.06–0.08, Cr = 0.80–1.00, V = 0.12 to 0.20. Heat treatment: Heated to 865 deg. cent., held ½ hr. and air cooled, then heated to 570 deg. cent., held ½ hr. and air cooled.)

used for cutting heavy structural sections of hot and cold steel, together with the chemical analysis and heat treatment used for these blades, there may be others which have been found to give greater success.

Fig. 4 shows a saw blade used for cutting hot steel and the relation of the saw blade to the beam about to be cut. The teeth of this saw blade are machine punched and later widened with an air-driven swaging tool. Swaging is necessary for running clearance as the sides are not hollow ground, although a saw-tooth grinder is used to shape the teeth. Hardening of the teeth to about one-half their depth prolongs the service of the saw blade. Running at a speed of 18,000 ft. per min., this saw blade is used for cutting red-hot steel.

Fig. 5 shows a saw blade used for cutting cold steel. The early cold saws had blades without nicks, the edge of the blade being smooth. Later it was found that by nicking the cutting edge a faster cutting could be obtained and this is the practice at the present time. The nicks as shown are driven with an air chisel which also widens the edge of the saw blade. The peripheral speed of the saw blade should be from 24,000 to 26,000 ft. per min. for successful cutting.

The saw blades, Figs. 4 and 5, are flat disks which are sheared from a rolled plate. The plate is rolled in a plate mill shortly after a roll change to get as uniform thickness of the plate as possible without having to grind the sides. It should be noted, however, that the grinding of the sides, particularly the hollow-

ground sides, with milled and ground teeth, must necessarily, if correctly done, produce a better balanced blade than a disk not so treated.

All circular saw blades running at a high speed have to be tensioned in order to be safe and to make a straight cut. The tensioning process can be said to be similar to the tightening of the spokes in a bicycle wheel except in a reverse manner. That is, the imaginary spokes in a saw blade, if that term may be used, have to be elongated to distribute and to partly equalize the tangential stress set up when the saw blade is rotating at a high rate of speed. Tensioning has to be done from both sides of the saw blade and with considerable care so as not to dish the blade.

As yet no practical means, fixed rule, or measure, so far as the author knows, has been devised whereby the tension can be put

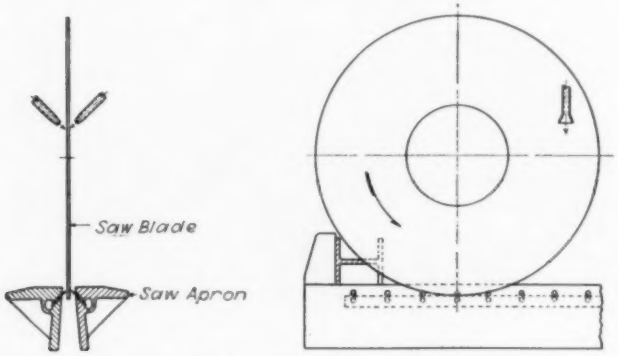

FIG. 6 WATER SPRAYER FOR HOT AND COLD SAWS

into a saw blade with any scientific certainty. At present this operation is left wholly to a sawsmith who with the aid of a hammer, anvil, and a short straightedge does the work according to vision and a sense of touch.

The cooling of the saw blade when sawing cold steel is of considerable importance. Any excessive amount of water flowing down with the saw blade to the line of contact will retard the cutting and also produce a hardened surface at the ends of the material being cut. This hardness was found to be from 45 to 80 Shore scleroscope, and difficulties were experienced when the ends of the beams had to be machined.

A number of tests were made and it was found that when the cooling water is applied as indicated in Fig. 6 no appreciable hardening takes place in beams of less than 300 lb. per ft. Water pressure at 500 lb. per sq. in. is used to cool the saw blade and to clear the teeth or nicks of cuttings.

To determine the relative worth of saw blades a test was carried on over a period of eight months. A total of 103 saw blades were used and grouped as per Table 1. The product sawed was the normal daily run made up from any and all sections. No record was kept of material being removed by the saw blade, neither was any record kept of redressing, although approximately 800 cuts per saw dressing is a fair average. The test was terminated when 49 of the 103 saw blades had been scrapped as unfit for further service.

In all probability if the test had continued the ratio of number of cuts per scrapped blade would not have altered materially. The table shows that, in Group 1, four blades give less than one thousand cuts, two blades give less than two thousand cuts, etc. The greater number of failures occurred before the saw blade had made 5000 cuts, and thus far there seems to be very little difference between the straight and the hollow-ground blade although thereafter the hollow-ground blade has some advantage.

The failure of a saw blade is generally from cracking at the nicked edge, the crack starting at the periphery and then continuing in a more or less radial line toward the center. The cause may be laid to a number of variables such as homogeneity of material and method employed when machining the saw blade, cross-section, and quality of material being cut, as well as the cooling of the saw blade while cutting. Other factors such as the tensioning of the saw blade and the rate of feed are very important items which now are left to the operator's skill.

The life of a saw blade would be prolonged if the saw approach and the rate of feed were automatic and errors on the part of the operator were thus eliminated. The author has no remedy to offer for the difficulty of putting the proper tension into a saw blade; indeed, this problem may be food for thought to any one interested in this subject. As to the quality of the saw blade it goes without saying that a more homogeneous steel having the proper chemical constituents and the highest class of workmanship must necessarily be superior to any lesser quality.

SAW PERFORMANCE

A comparative test was run between the motor-driven belted saw and the direct motor-driven saw, as per Figs. 1 and 2, respec-

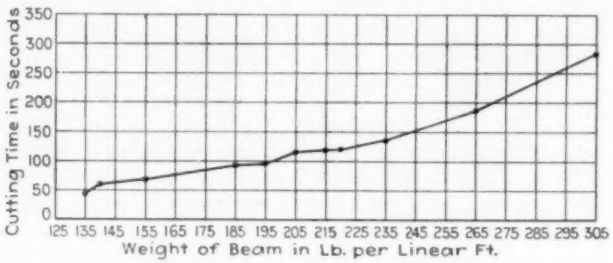

FIG. 7 RELATION OF WEIGHT OF BEAM SECTIONS AND CUTTING TIME

tively. This was done to determine the relative power consumption between the two saws cutting identical beams. The test showed that the belted saw requires approximately from 40 to 45 per cent more power to cut a given beam than does the direct motor-driven type of saw. In sawing, however, the actual cutting time is generally only a small fraction of the running time, and this has to be considered in a fair comparison of the two saws.

CUTTING TIME

A test was run to determine the actual time it takes to saw cold-steel beam sections under normal running conditions. The saw blade used was of the cold-saw type, Fig. 5, 61 in. diameter by $^{7}/_{16}$ in. thick, running at a peripheral speed of 26,000 ft. per min. The saw was of the belted type, as per Fig. 1, driven by a 300-hp. motor. With the hand-operated feed control the saw-drive motor load was held as near the rated motor capacity as possible. The weight of the Carnegie beam sections sawed and the average cutting time in seconds are given in the chart, Fig. 7.

The total cross-sectional area of beams as shown is 663 sq. in. and the total cutting time is 1319 sec. Therefore, the average cutting is approximately $^{1}/_{2}$ sq. in. per sec. The cutting time of this saw was estimated at 2 sq. in. per sec. for sawing cold steel. The saw capacity was based on experience in sawing standard structural sections, and from the foregoing test it is evident that the estimated capacity was too high.

The path of the saw blade as indicated in Fig. 4 shows that cutting takes place in both flanges as well as the web simultaneously, and this together with the heavier section accounts for the difference in time. Sawing beams of a similar section weighing more than 305 lb. per ft. will cause the saw blade to wear rapidly, and as the cutting is retarded the end surfaces of the beam become hard. The limited capacity of the saw which causes the slippage

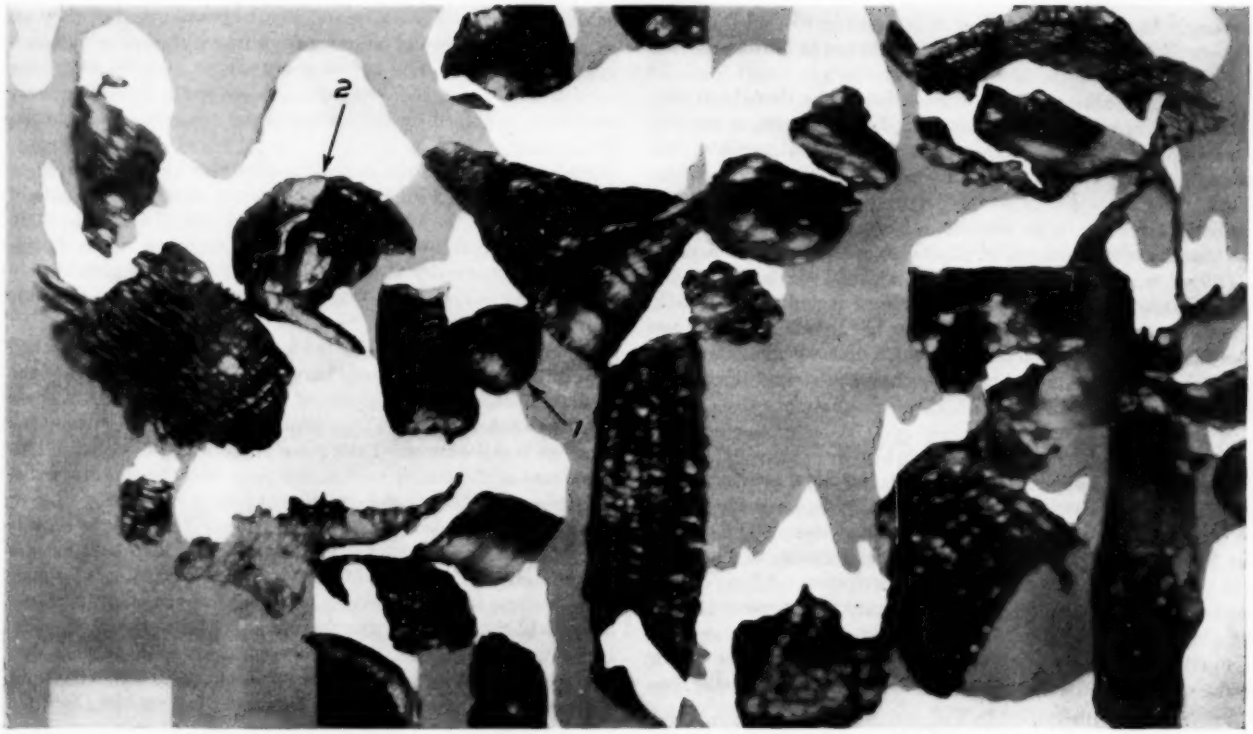

FIG. 8 SAW DUST FROM BEAM HAVING TEMPERATURE OF APPROXIMATELY 1400 DEG. FAHR.

FIG. 9 SAW DUST FROM COLD BEAM

of the saw blade without cutting is therefore indirectly the reason for the hardening of the beam. From this it can be seen that the cutting time is a very important factor, and a smaller saw cannot be used by allowing more time for the cutting.

For successful sawing the cutting capacity should be at least 1 sq. in. per sec. to avoid hardening of the beam ends. Added horsepower for the saw-motor drive will increase the sawing capacity, although there must necessarily be a maximum of

saw-blade contact after which it is impossible to cool the blade sufficiently to maintain the relative difference in hardness which alone makes it possible to hot-saw steel.

In sawing beams at temperatures of not less than 1400 deg. fahr., and of sizes as per the chart, Fig. 7, using a saw, as per Fig. 1, having a toothed saw blade running at 18,000 ft. per min., the average cutting time is approximately 1/8 of that given in the chart.

All the Carnegie beam sections as now rolled are sawed while the beams are red hot. The 425-lb. section having an area of 124.99 sq. in. can thus be cut in from 45 to 60 sec.

To cold-saw all Carnegie beam sections including the 425-lb. beam successfully, a more powerful saw has to be built. The saw blade should also, if possible, be of such a diameter that the blade will leave the first flange before entering the second during the sawing operation.

Principles of Sawing

A difference of opinion exists, which has been previously referred to in this article, as to what actually happens when a revolving disk cuts its way through a piece of steel. The process has been called friction, burning, fusing, cutting, or abrasion, and perhaps other names equally as descriptive. All, no doubt, have seen the large volume of brilliant sparks that passes off during the sawing operation. These sparks and cuttings, coming from either a hot or a cold saw, generally go by the name of saw dust. A very marked difference may be observed in the two kinds of chips.

To present some light on this subject magnified photographs of the chips removed by the saw blade are shown. A structural beam having a temperature of approximately 1400 deg. fahr. was sawed. The saw blade used was of the hot-saw type with teeth as shown in Fig. 4 running at a peripheral speed of 18,000 ft. per min. Saw dust collected from the cuts was sorted and the chips photographed, the magnification of the originals being 7.2 diameters. Fig. 8 shows the irregular shape of the chips.

Although the beam had a high initial temperature, additional heat was generated by the friction of the saw blade to cause oxidation along the edges of the chips. This oxidation caused the globules to form after the chips were removed from the beam. A typical globule may be noticed at the point of arrow 1. Some of these globules expand until they explode, and a case of this may be noticed at arrow 2. The brilliant sparks seen in sawing steel are the globules as they form, expand, and explode during their travel.

The chips when examined under a microscope will show on the one side lines caused by the face of the saw blade in its travel similar to the lines left at the end of the beam after sawing. These lines are in the line of travel of the saw blade and lengthwise of the chips and not crosswise, which may have been expected because of the toothed blade. On the side of the chip that faced the beam when sawed a tearing action is indicated, which shows very clearly on the photograph. It is therefore evident that the chips were not in a molten state when they were removed from the beam.

For comparison a cold structural beam was sawed having a temperature of approximately 60 deg. fahr. before sawing, the saw blade used being of the cold-saw type with nicked edge, as per Fig. 5, running at a peripheral speed of 26,000 ft. per min. The saw dust was sorted and photographed in the same manner as that from the hot saw. Fig. 9 shows the chips, which in this case resemble flakes. The heat produced by a cold saw is caused entirely by friction, and as compared to the hot saw a more rapid oxidation takes place because of the smaller chips or flakes. There are not any globules shown in this photograph as they were eliminated when the saw dust was sorted. These globules do exist, however, and are given off in a large volume, but they always either explode and become grit or fuse with each other forming a solid mass. The reason there are no globules along the edge of the flake is that the flake adheres to the face of the saw blade and is chilled by the cooling water before the globule can be formed.

The saw blade in its travel has also here caused grooves or lines which under a microscope show very clearly on the side of the flake facing the blade. On the other side of the flake there is no indication of the saw blade, instead a tearing action is shown. It is also noteworthy that the flakes are curved approximately to the same radius as the saw blade in line of travel. An oxide film covers the flakes.

If two pieces of steel having the same characteristics are rubbed against each other sufficiently hard, the most work and hence the greatest heat will be at the line of contact. Now if one of these pieces is cooled and heat thus eliminated by outside means, the heat line is shifted toward the piece of steel not so cooled. This is because of the stored heat in this piece and the continued disturbance of the fibers and consequent heat generation. In sawing, for a similar reason this heat line is located somewhere outside the face of the saw blade. The distance is very small and approximately the thickness of the chip. This explains why lines from the saw blade can be seen on the side of the chip that faced the saw blade as well as the tearing action of the opposite side. By actual measurement the average thickness of the hot-saw chip is about 0.01 in. and those from the cold saw 0.003 to 0.004 in.

The hot-sawing action of steel is essentially a rubbing, heating, and a tearing action. The necessary rubbing to create sufficient heat for sawing depends on any prior heat in the steel to be sawed, the feed pressure, and the speed of the saw blade, as well as the continued cooling of the edge of the blade. Hot-sawing of steel is possible when the friction between the steel to be sawed and the saw blade exceeds the tensile strength of the heated steel at a distance from the saw blade equivalent to the thickness of the chip.

Discussion

George C. Farkell.[2] The possibilities of hot-sawing steel sections so obviously depend upon the ability of the blade to withstand the work that this part of the hot saw deserves the most careful attention. The remarks made by the author on the principles of hot-sawing merit the most careful consideration and indicate a tearing action at the time the blade is in contact with the hot steel. This action seems to be similar to the cutting action of milling operation on cold steel, so that the fundamental principles involved are probably much the same.

The variables when hot-sawing which have an influence on the life of the blade, listed roughly in the order of the effect, are the temperature of the steel being sawed, the cooling of the blade, the rate of cutting as determined by the feed, the circumferential speed of the blade, the shape and thickness of the tooth, the chemical and physical properties of the blade, and the shape of the section being sawed. A thorough investigation of these variables to determine their effect on the life of the blade would give very valuable information for the designer as well as the operator of hot saws.

In the hope of adding something to the information now available on the action of the hot saw blade when sawing steel, the writer wishes to present the following practical results observed when sawing large rounds of from 20 to 95 sq. in. in section intended to be manufactured into large seamless pipe. Sliding frame saws are used, the blades of which are 50 in. in diameter

[2] Superintendent, Rolling Mills, National Tube Company, Lorain, Ohio. Mem. A.S.M.E.

by 1/4 in. thick, running at a peripheral speed of 16,200 f.p.m. when new, and at 13,500 f.p.m. when the blade is finally discarded at 41 1/2 in. in diameter. These blades are furnished by experienced saw manufacturers whose recommendations for physical and chemical properties and the tensioning and grinding of clearance in the sides of the blade are accepted. The form of tooth furnished, however, is specified by us and is shown by Fig. 10.

With these blades it is possible to saw the largest rounds at a rate of 6 sq. in. per second as long as the teeth are kept cool.

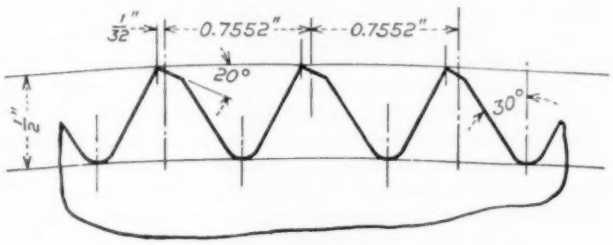

FIG. 10

As soon, however, as there is evidence of heating of the points of the teeth, as shown by the tooth being red when entering the cut, the power required rapidly increases and feed must be reduced. The blade must then be changed. Under such conditions the teeth will be found somewhat in the condition shown by Figure 11. Such a blade will require a reduction diameter of about 1/4 in. to bring back the tooth to the original contour.

FIG. 11

An examination of the cuttings taken at different times during which a blade is in service indicates that the cuttings up to the time the blade gets dull have very much the same characteristics, all being well represented by Fig. 8 of the paper. This fact indicates that the sawing action is very similar up to the point when the tooth starts to lose its cutting ability and that when this takes place deterioration is rapid. This would, it is believed, indicate that the form of tooth is important and that study should be given to this factor to get the most efficient contour for cutting hot steel which is best adapted for effective cooling.

The temperature of the piece being sawed has obviously an important bearing on the problem and is such that it is doubtful if results obtained on the average life of a large number of blades are of any great value in arriving at a conclusion. It is frequently necessary, regardless of blade life, to saw material which is very cold due to delays in getting the product to the saws. Under such conditions, blades cannot be changed, sawing approaches a cold-sawing operation, and the life of the blade is short.

It is believed that best performances are better indicators of service, because these results probably indicate that more uniform conditions of temperature prevailed. As an indication of the effect of temperature, we find that under best conditions we are able to saw 16,000 sq. in. per 1/16 in. of blade diameter when sawing 5 1/4 in. diameter rounds which require about one-half minute longer from the pits to the saws as compared with 28,000 sq. in. for 1/16 in. of blade diameter when sawing 11 in. diameter rounds. The 11 in. is hotter, not only on account of shorter time from pits to saws and having less radiating surface, but also on account of sawing fewer units.

Effective cooling of the blade is vital. In addition to the methods referred to by the author, we have made provision so that the bottom edge of the blade runs in a pool of water with a high pressure jet pointed tangentially at the teeth on the bottom of the blade. With a blade properly cooled, changed as soon as indication of heating of the points of the teeth is observed, we have not found any difficulty in keeping the teeth free of cuttings, although at times of emergency when blades cannot be changed the spaces between teeth are at times found plugged with cuttings which cannot get out due to the upsetting of the points of the teeth.

An investigation in the art of hot-sawing steel as practiced at the various works will show considerable variations, which would indicate that careful investigations to determine blade characteristics for greatest life would give very interesting results, in regard to which the writer has found but very little accurate information available.

J. J. DUNN.[3] A statement of experience in the limited field of hot-sawing rounds may be of value. The Mannesmann process for seamless tubes is now requiring a very large tonnage of rounds, varying in diameter from 3 in. to 12 in. and in weight from 25 lb. to 5000 lb. and over. As an average the hot saw for this work must make 160 cuts per hour on 4 1/2-in. diameter steel. It must be capable of cutting 3-in. steel at a rate of at least 33 cuts per minute, and have capacity for the largest diameter required.

At one bar mill the sliding-frame type of saw was used for about ten years. When this mill was rebuilt, at a time when this type of saw was growing in favor in preference to the pendulum and drop saws, careful consideration of the subject led to the selection of the drop type for the new installation. The reasons for the selection were:

(1) Saw chips could not be kept out of the slide of the saw frame previously used. This caused delays and increased cost of upkeep
(2) Variable resistances to motion made it difficult to maintain the rate of cutting required by the smaller diameters
(3) The cost of the sliding frame type was greater than that of the drop frame type.

Reasons (1) and (2) could probably have been overcome by good design, but nearly 15 years' use of the drop-frame design selected has proved that no serious error was made in the choice.

The design of these drop-frame saws embodied no unusual features, with the exception that they were considerably heavier than was then the practice. The following data regarding details of design and service may be of interest:

Motor. Induction type, 150 hp., three phase, 60 cycle, 2200 volts, 695 r.p.m., full-load speed. Driving pulley 24 in. diameter by 18 in. face, giving a surface speed of 4365 f.p.m.

Saw Arbor. The saw arbor has journals 4 3/4 in. in diameter by 14 in. long, spaced 28 in. centers. These run in self-aligning babbitted shells; lubrication is the gravity type with 12 ft. head. The life of these bearings is about 225,000 tons, requiring 1,500,000 cuts.

Two types of roller bearings have been tried and discarded because they gave a life less than half that of the babbitted bearings without any compensation advantages.

The pulley on the saw arbor is 12 in. in diameter. It is grooved parallel to the axis with flutes 3/16 in. wide by 1/8 in. in depth, spaced about 5/8 in. center to center. These grooves are effective in reducing the belt tension.

Belt. The belt is of selected leather 14 in. wide by 38 ft. 6 in. long. The average life is about 90,000 tons.

Saw. The saws are 52 in. diameter, 5/16 in. gage. They are used until the diameter is reduced to 46 in. Peripheral speed

[3] General Superintendent, Ellwood Works, National Tube Company, Ellwood City, Pa. Mem. A.S.M.E.

of the saws varies from 19,000 to 16,700 ft. when the saw is discarded. The saw tooth is a sharp V, $^3/_4$ in. pitch and $^{19}/_{32}$ in. in height to the bottom of fillet of $^7/_{32}$ in. radius. In grinding no attempt is made to maintain the form with accuracy. Saws are ground after eight hours' service. This represents cutting an average of 16,500 sq. in. of metal.

Cost of Maintenance. The heaviest item in the cost of maintenance is repairs to the hydraulic feed mechanism. The average total maintenance cost for six months' period was $0.023 per ton, or $0.19 per 1000 sq. in. of metal cut.

J. M. Lewis.[4] The friction saw blade operating at a rim speed in excess of 19,000 f.p.m. cuts steel while cold by a melting action. Each point on the blade periphery rubs against the work, creating friction which causes both the blade and the work to be heated. As each point on the blade passes out of the work, it is cooled off in the air before passing down again past the work, while the work is continuously being heated by the blade periphery.

It is essential to keep the blade periphery cold as it passes down again past the work. It should not become red hot on the periphery. If it shows a red heat, the cooling should be assisted by applying cooling water in some manner directly against the rim, in sufficient volume and pressure to penetrate the air film surrounding the blade periphery, so as to keep the blade cold during the entire cut.

In cutting low-carbon structural steel the blade heats the material to a putty stage rather than a liquid stage, and to assist the removal of the heated metal in this stage, it is necessary to indent the periphery of the blade. High-carbon steels (above approximately 0.35 per cent carbon) change readily to a liquid stage under the action of a friction saw blade and the blade periphery need not be indented.

If the carbon content of the steel being cut is high enough to allow a tempering action, the sawed surfaces will be tempered to a depth of only about $^1/_{64}$ in. For low-carbon steel there is no hardening effect on the sawed surfaces.

The usual method of redressing friction saw blades for cutting low-carbon steels has been to nick the periphery with a cold chisel. A newer and better method has been developed whereby the blade periphery is hobbed by a combination serrating and topping spiral hob which forms a uniformly indented periphery and also trues the periphery concentric with the bore of the blade, removing the skin surface from the rim, which may have developed surface cracks during the sawing operation. Side-milling cutters trim the burred sides of the blade during the hobbing operation, leaving only a small amount on each side of the blade for clearance.

S. M. Weckstein.[5] From the discussions which have preceded and referring to Fig. 3 in the paper, the writer wishes to bring out a few points on the design of hot and cold saws and the bearing application problem which has come to attention within the last few years. He will limit his remarks only to the design of the arbor and will make no reference to the blade.

In our own mills we had considerable difficulty with the operation of the bearings on the saw arbor. In order to eliminate costly shutdowns, we decided to make some tests on the use of Timken bearings. After considerable development work, we worked out a design which has been in operation for over three years and has given very satisfactory service. Based on the experience and the very satisfactory operation, quite a number of steel mills throughout the country have adopted this design and are using Timken-equipped hot and cold saws. In the application of bearings on saw arbors, quite a number of points must be considered:

(1) High speed of operation
(2) Extremely heavy load, which is also a shock load
(3) Deflections in the saw-arbor spindles due to the extremely high belt pull and the overhung saw blade.

It has been our experience that most of the bearing difficulties encountered have been due to deflection in the saw arbor and consequent unbalanced loads. One of the larger mills in the country has quite a battery of Timken-equipped saws, and it advises that the secret of the proper operation of these saws is the periodic checking of the saw arbor to make sure that it is not bent and unbalanced in any way.

Another important point which should be considered in the design is the provision for a proper lubrication system. We have found that, due to the large size bearings required and due to the high operation speeds, the best type of lubrication system is a continuous lubrication system supplying a stream of oil of $^1/_{16}$ to $^1/_8$ in. in diameter to the bearings by gravity feed. This oil is taken away from the bearings and pumped from the system back to the gravity tank.

It has also been our experience that a number of jobs which operated originally on plain bearings and were changed over to anti-friction bearings gave considerable trouble both on the plain bearings and anti-friction bearings until such a lubrication system was worked out.

W. Trinks.[6] At Carnegie Tech we have a course in mechanical engineering of steel works. Among other machinery, the students design a hot saw. It is comparatively easy to determine the smallest feasible diameter of the saw blade, but difficulty arises in determining the thickness of that saw blade. It is obvious that the thicker the saw blade, the more material is removed by it, and the greater is the power requirement. Consequently the saw blade is always made as thin as possible, without having it go around a corner. The question which the writer would like to have answered is, How thin can the saw blade be made in a given case without having it go around a corner? Beams must be sawed so straight that no further finishing of the ends is needed.

The speed of cold saws is greater than that of hot saws, because hot saws can cut at a lower speed than cold saws. Has any one tried to run a hot saw as fast as a cold saw? If so, what happens?

Author's Closure

The information as to the minimum thickness of a given diameter of saw blade is not available. The user generally arrives at the most economical saw-blade thickness by trial, and information obtained thus is based on the average of both the temperature and the section of the material being sawed.

One user desiring to increase the diameter of a $^7/_{16}$-in. thick saw blade from 60 in. to 66 in. to allow for more wear, later found it necessary to decrease the diameter to 62 in. to avoid "going around the corner." The material being sawed was red-hot structural steel up to 425 lb. per lineal foot. The most desirable ratio of thickness to the diameter of a saw blade will generally be found between 0.005 and 0.009 to 1, for sawing both hot and cold steel. This ratio of thickness to diameter will serve as a guide in arriving at a thickness giving the best result. In regards to speed it has been found that a saw blade, when sawing cold steel running at 20,000 f.p.m., has a very much shorter life than a blade when running at 24,000 f.p.m. or over.

Forces Acting on Roll-Neck Bearings

Report of the Special Research Committee on Heavy-Duty Anti-Friction Bearings

By W. TRINKS,[1] CHAIRMAN, AND J. H. HITCHCOCK,[2] RESEARCH ASSOCIATE

FOR the intelligent design of anti-friction bearings for application to roll necks, the average load to which the bearings are subjected must be known with reasonable accuracy, and the maximum load to which the bearings will at any time be subjected must be known at least approximately. The reasons for these requirements are the following: Unless flaws exist in one or more of the balls, the final failure of a bearing is usually caused by fatigue due to many applications of the average load. A bearing can withstand occasional loads considerably higher than the average load, but its capacity to withstand such loads without injury is not unlimited, and an excessive load might bring about bearing failure. Consequently, we must know the average load accurately and the maximum load approximately.

There are now available five methods for determining the bearing loads on roll-neck bearings. The first, the use of Brinell balls and plates, is suitable for the determination of maximum loads only. The hydraulic cylinder, second, and the strain gage, third, are suitable principally for the determination of average loads. The fourth and fifth methods, of comparatively recent development, are the telemeter, or carbon pile, and the electrical condenser. These latter two methods are practically free from inertia effects and may be used to determine either maximum or average loads.

The efforts of the committee up to the present time have been directed largely toward the collection, coordination, and analysis of existing data. It has been attempted to obtain and evaluate all existing data on this subject, from tests in other countries as well as our own.

Valuable data on hot-rolling steel shapes were obtained from the results of tests made by Dr. Johann Puppe, as published in his book, "Untersuchungen über Walzdruck und Kraftbedarf beim Auswalzen von Knuppeln, Winkeln, U and I Eisen." Equally valuable data on cold rolling were found in a report of tests made by Pomp and Seibel, published in "Mitteilungen aus dem Kaiser-Wilhelm Institut für Eisenforschung" under the title, "Walzdruck und Walzarbeit beim Kaltwalzen von Metallen." The results of extensive tests made by the Timken Roller Bearing Company constituted a further source of data. Recent tests made by this company have not been completely evaluated at the time of writing this paper. The results of these tests can be expected to add a great deal to our knowledge of rolling pressure. Tests results were also obtained from S-K-F Industries, Inc., Rollway Bearing Company, Jones and Laughlin Steel Corporation, National Tube Company, and Republic Steel Corporation. Because this paper is read under the auspices of the Iron and Steel Division, the data presented herein apply only to iron and steel. Valuable data have been and still are being collected on other metals, including copper, brass, zinc, and aluminum, which, for the reason stated, will not be included in the present paper. It should be mentioned that test data were being accumulated rapidly in midsummer when this paper was written. Consequently, the present available knowledge of rolling pressures is considerably in advance of that incorporated in this paper. At the time of writing, sufficient information has been compiled, not only to allow some conclusions to be drawn, but to indicate the direction in which additional tests should be made.

Review of Forces in Rolling Mills

For a thorough understanding of the forces to which roll necks are subjected, a review is advisable of the nature of the forces which occur in rolling mills.

A rolling mill deforms material between the rolls by means of compression. The resultant force which is exerted on the material being rolled, which is hereafter called the bar, is the compression force which acts at right-angles to the direction of rolling. This statement refers only to rolling in one single stand, and in that case, only to rolling at constant speed. If rolling is done at varying speed, forces in the direction of rolling enter into the problem through inertia effects. If the rolling is done in several stands continuously, forces which cause tension or compression in the bar may exist between successive stands. However, if we limit ourselves for the present to rolling in one stand at one constant speed, the force which is exerted between the rolls and the bar is solely a compression force acting at right-angles to the direction of rolling. In that case the bar is free at both ends and cannot, in general, take up any force in the direction of rolling. As exceptions to this statement, we must note the very small force which is caused by the friction of the rollers on the roller table, and the very small force which is due to the speed change of the bar, which enters the rolls at a low speed and leaves at a slightly higher speed. Both of these forces are usually less than 1 per cent of the compression force, and can therefore be neglected. All of the foregoing statements refer solely to the resultant force between the rolls and the bar. It should be fully understood that local tangential forces are exerted at various points of the contact area between the rolls and the bar; and it must also be understood that such tangential forces cancel each other, leaving in effect only the resultant force at right angles to the direction of rolling. This resultant force which acts between the rolls and the bar will hereafter be called the separating force.

The separating force may be considered the product of the projected contact area by the average pressure which is distributed over that area. The projected contact area is that area, common to the bar and the roll, which would be seen through the roll if the latter were transparent. The projected contact area

can be determined by simple methods of descriptive geometry, but its determination does not properly constitute a part of this paper. The determination of the average pressure, however, and of its relation to various factors, constitute the problem with which we are concerned.

There is an essential difference between the hot and cold rolling of steel due to the fact that the hardness of steel is very much greater at low temperatures than at usual temperatures of hot rolling. Consequently, much greater average pressures are encountered in cold rolling than in hot rolling, which result in the

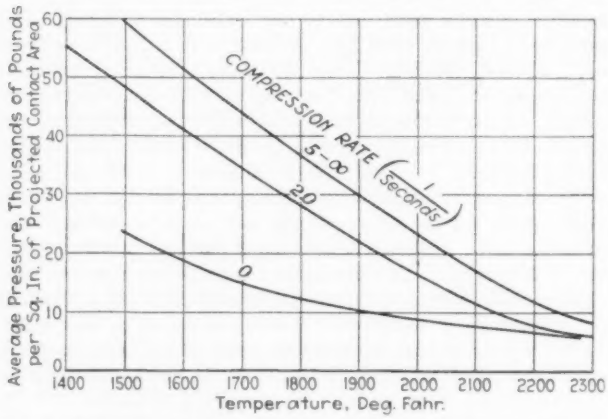

FIG. 1 RELATION BETWEEN AVERAGE PRESSURE, TEMPERATURE, AND COMPRESSION RATE FOR MILD STEEL, 0.10 TO 0.20 CARBON
(For square sections and values of contact length/thickness less than 1.)

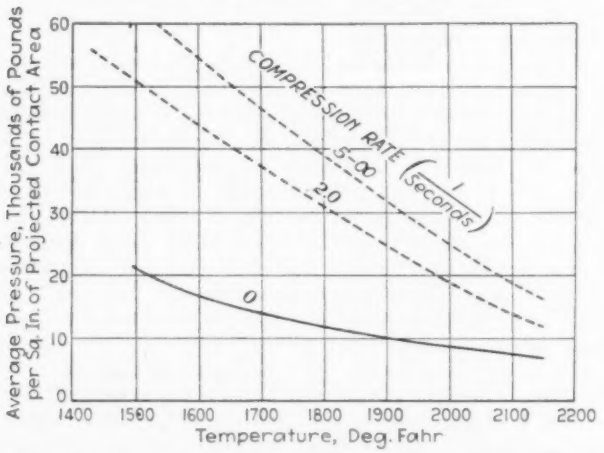

FIG. 2 RELATION BETWEEN AVERAGE PRESSURE, TEMPERATURE, AND COMPRESSION RATE FOR HARD STEEL, 1.00 CARBON
(For square sections and values of contact length/thickness less than 1.)

deformation or flattening of the rolls to a considerable extent. This effect will later be considered in detail.

HOT ROLLING

The average pressure in hot rolling depends upon the following variables:

a Temperature of bar
b Composition of bar
c Compression rate[3]
d Internal friction of bar
e Friction between bar and rolls.

[3] The compression rate is determined by means of the formula draft/(thickness × time) in which the time is that required to pass through the angle of contact. The unit in which the compression rate is expressed is therefore 1/seconds.

The effect of temperature upon the average pressure has long been known. This is also true, to some extent, of the effect of compression. The influences of compression rate and of the internal and external friction are not well known; in fact, the influence of external friction was not even suspected.

A great mass of more or less fragmentary data has been collected interconnecting these variables, and the problem immediately arose to construct an equation or a chart which would represent their relation. But the preparation of a chart connecting six variables presents great difficulties, and especially so if the data are very meager. Consequently, we shall have to be content

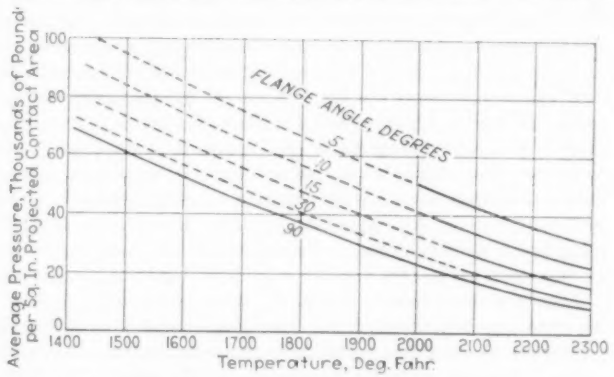

FIG. 3 EFFECT OF FRICTION BETWEEN THE BAR AND THE ROLLS AT HIGH COMPRESSION RATES FOR MILD STEEL, 0.10 TO 0.20 CARBON
(For values of contact length/thickness less than 1.)

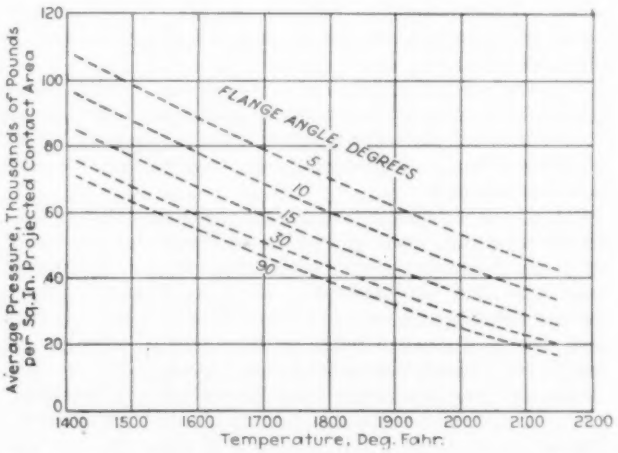

FIG. 4 EFFECT OF FRICTION BETWEEN THE BAR AND THE ROLLS AT HIGH COMPRESSION RATES FOR HARD STEEL, 1.00 CARBON
(For values of contact length/thickness less than 1.)

for the present with charts showing only partially the relation between the average pressure and the factors upon which it depends.

The curves of Fig. 1 illustrate to some extent the effect of temperature and compression rate upon the average pressure developed in hot-rolling mild steel. The curves of Fig. 2 show the partial influence of the same factors for high-carbon steel of the composition indicated. In each case the curves apply to sections which are nearly square, rolled with the compression rates indicated. The curve of zero compression rate in each of these figures represents the static resistance to compression. The values used in plotting these curves were taken from "Walzwerkswesen," by J. Puppe.

The curves of Figs. 3 and 4 indicate to some extent the effect of external friction. In these latter figures, the values given in

the column at the right-hand side refer to flanged sections and denote the size of the flanged angle of the section being rolled. They apply therefore to the roughing and finishing passes in the rolling of I-beams, channels, and rails. This angle may be defined as the inclination of the inner wall of the flange from the vertical. It is obvious that as the inner wall of the flange approaches the vertical, the flange angle becomes smaller and the force due to external friction increases. The approximate magnitude of the resulting increase in pressure can be observed in the figures. The curves for which the flange angle is 90 deg. apply to rectangular, almost square, sections, and are the same as the curves of high-compression rate in Figs. 1 and 2. In each figure shown, the dotted portions of the curves represent data of uncertain accuracy, or approximations which have not yet been checked by test data.

In each figure shown, the dotted portions of the curves represent data of uncertain accuracy, or approximations which have not yet been checked by test data.

The influence of compression rate upon the average pressure is due to the internal friction, or viscosity, of the bar being rolled. Steel above the critical range of temperature where all hot-rolling is being done resists change of shape in the same manner as tar, pitch, clay, or plasticene, and its resistance increases with the rapidity with which the change is produced. The compression rate, as indicated in footnote (3), is a measure of the rapidity with which the change is produced. The resistance to change, or internal friction, therefore increases with increasing compression rates; and since the force due to internal friction must be overcome by rolling pressure, the latter also increases. This proportional relation between average pressure and compression rate does not apply, however, to all values of the latter. For values of compression rates equal to or greater than about 5 per second, the average pressure remains sensibly constant. This is probably due to the fact that at high compression rates the bar being rolled is heated considerably, and thereby softened, by the compression.[4]

The effect of internal friction upon the average pressure is very marked in the rolling of thin strips, for the following reason: The surface layers of the bar being rolled which are in immediate contact with the roll surface are considerably impeded by that contact from lending themselves to the general change of shape. As a result, a very large part of the deformation must occur within the inner layers of the bar, against the restraining influence of the outer layers. It is at once evident that, as the bar becomes thinner and thinner, a point is reached at which the deformation becomes very difficult. Consequently, the average pressure for rolling very thin sections is greater than for thick sections, other effects being equal. It is very difficult to obtain test data showing the effect of internal friction as a separate and distinct factor from external friction, because each of these friction effects is present in some degree in every case. Also, discrepancies are often found in test data, such as that shown in Fig. 5. In this figure, there is no apparent reason why the two curves for strips should not coincide, and yet there is a difference between them of approximately 60 per cent of the higher value. This illustration is typical of many baffling results which are found, and the work of this committee will be incomplete until sufficient test data are obtained to make known the reasons for such wide variations. It is felt that all such apparent discrepancies will cease to exist when all the facts of the case are known.

The external friction between the rolls and the bar being rolled

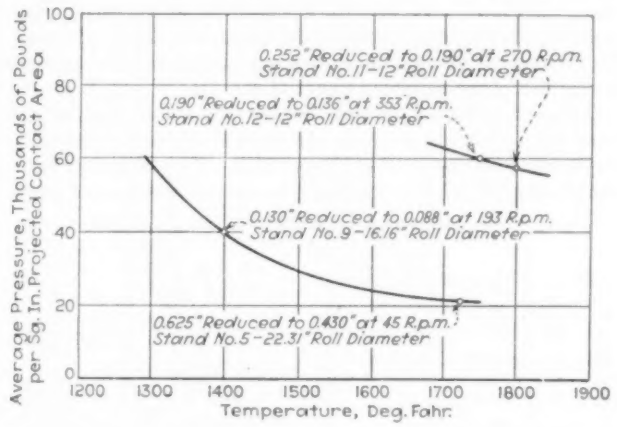

FIG. 5 TYPICAL DISCREPANCIES IN TEST RESULTS, SHOWING THE NEED FOR FURTHER TESTS
(Mild steel strips rolled in continuous mills.)

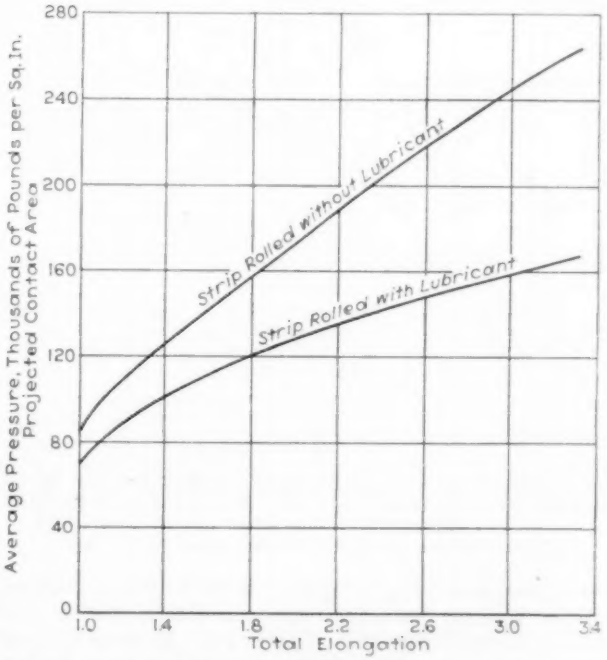

FIG. 6 EFFECT OF FRICTION BETWEEN THE BAR AND THE ROLLS AT HIGH COMPRESSION RATES IN COLD ROLLING MILD STEEL (0.10 CARBON) BASED ON RIGID ROLLS
(For values of contact length/thickness between 6.0 and 17.0.)

has an effect upon the roll pressure which was not suspected until recent test data brought it to light. The force due to this friction acts, of course, in a direction tangential to the surface of the roll. As long as both ends of the bar are free (that is, unless the bar is rolled in a continuous mill), the force due to external friction must be overcome by the rolling pressure alone. The latter must act in a vertical direction, as explained earlier, and at some distance x from the vertical center line of the mill. The additional

[4] The statement that the specific resistance to compression does not grow perceptibly beyond compression rates of 5 per second may be doubted by those who have lived with rolling mills and have watched the destructive effects of higher and higher speeds, particularly in blooming mills and other mills of heavy type. However, it is practically certain that the destructive effect of high speed is due entirely to stress caused by impact. If a small but long hot bar is suddenly gripped by the rolls, only the front end is accelerated the maximum amount because the bar is ductile and can be stretched. If, on the other hand, a heavy ingot is gripped by the rolls and accelerated, practically all of the mass is accelerated instantaneously, which produces enormous stresses.

rolling pressure required to overcome the external friction is then equal to

$$\frac{\text{external friction force} \times \text{radius of roll}}{x}$$

The length x of the moment arm at which the resulting separating force acts varies with the shape of the section rolled, with the uniformity of temperature of the bar, and with other factors. For rectangular sections under ordinary conditions it is approximately 2/3 of the projected length of contact.

It should be pointed out here that the effects of internal and external friction are cumulative. As the internal friction increases, the pressure increases, as has been noted. The tangential force due to external friction is a function of the pressure, and must

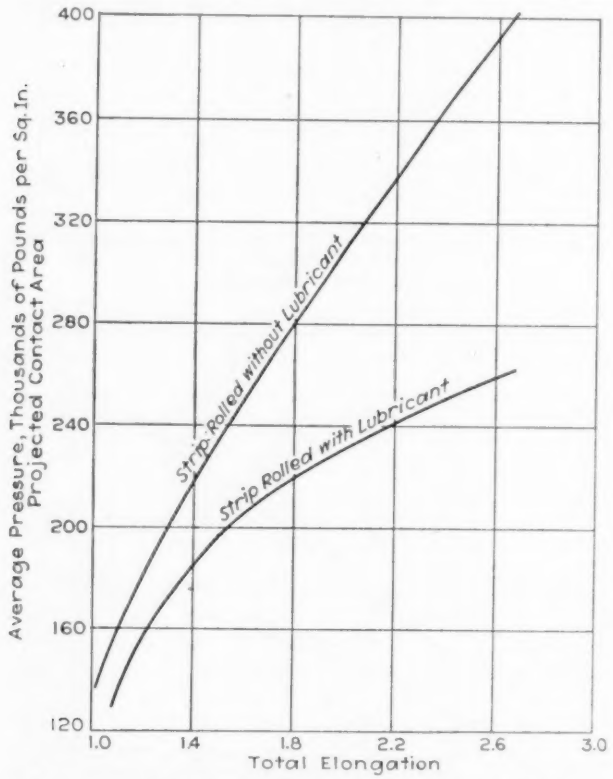

FIG. 7 EFFECT OF FRICTION BETWEEN THE BAR AND THE ROLLS AT HIGH COMPRESSION RATES IN COLD ROLLING MILD STEEL (0.63 CARBON) BASED ON RIGID ROLLS
(For values of contact length/thickness between 6.0 and 15.0.)

increase also as a result of increased internal friction. But we have just observed that increase in external friction must be overcome by increased pressure. Consequently, the pressure must continue to increase until equilibrium is reached, which means that an increase in internal friction produces a more than proportional increase in pressure. Examples of test data illustrating this point will be seen in the curves for flanged sections, Figs. 3 and 4, and in Figs. 6, 7, 12, and 13 under cold rolling.

In the very near future, test data on the hot rolling of alloy steels of various compositions are expected to be obtained. In the meantime, the data given in Table 1 will be of value. The table gives the ratio of the power required for rolling various alloys to that required for rolling mild steel at the same temperature. Inasmuch as the pressure is approximately proportional to the power required, these ratios can be used to determine the approximate pressure required for rolling alloy steels of the compositions given. The ratios were computed from a chart published in the Dec. 12, 1929, issue of *Stahl und Eisen*.

COLD ROLLING

In cold rolling steel, the average pressure depends upon the following factors:

a Elongation from annealed condition
b Compression rate
c Composition of bar
d Internal friction of the bar
e Friction between the bar and the rolls
f Modulus of elasticity of the roll (indirectly).[5]

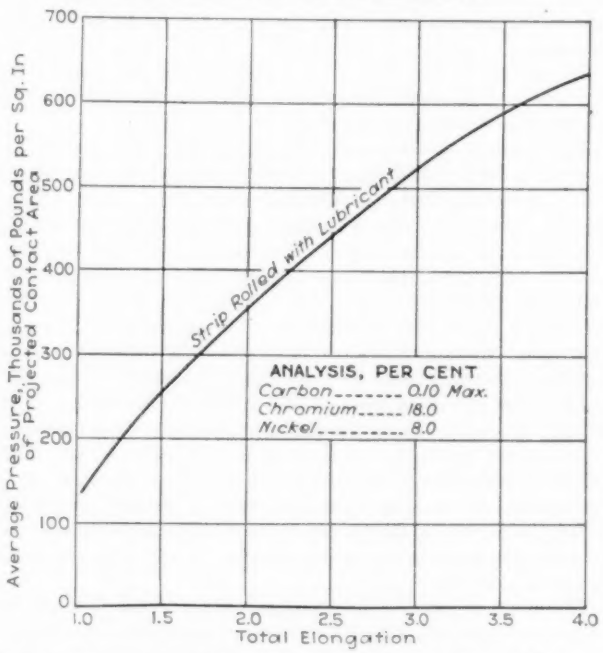

FIG. 8 PRESSURE FOR ALLOY STEEL COLD ROLLED UNDER TENSION AT HIGH COMPRESSION RATES BASED ON RIGID ROLLS
(For values of contact length/thickness between 2 and 5.)

TABLE 1

Material				Rolling temperature, deg. fahr.	Ratio of power required to that of mild steel at the same temperature
Fe	Ni	Cr	Mo		
100	..	..	..	2300	1.00
50	50	..	..	2120	1.62
20	63	17	..	2102	2.31
16	62	15	7	2102	3.86
..	80	20	..	2102	3.08
..	100	..	..	2102	1.27

With the exception of the first and the last, these factors are the same as those which determine the average pressure in hot rolling. The statements previously made regarding the extent of our knowledge of them apply here with equal force. Because of the need for further data, we shall have to be content, as before, with the charts showing only partially the relations between the average pressure and the factors which determine it.

The curves of Figs. 6, 7, and 8 are based on the cold rolling of low-carbon steel, high-carbon steel, and alloy steel, respectively, each having the composition indicated. In these figures, the abscissa is total elongation, or the length of the bar after rolling

[5] The average pressure in cold rolling is directly dependent only upon factors *a* to *e*. The modulus of elasticity of the roll has an indirect effect, the reason for which will be explained later.

divided by the length when the previous hot rolling or annealing was completed. The values of pressure in these three figures are based on the assumption that the rolls remain rigid.

As we observed earlier, in cold rolling the rolls are deformed or flattened very appreciably. This deformation has a distinct effect upon the calculated average pressure, as will be understood after consideration.

Fig. 9 illustrates in cross-section the reduction in thickness of the strip by a roll. Let us assume for a moment that the roll remains rigid and that its surface is truly cylindrical, as shown by the arc marked (10)-(9). A strip the entering surface of which is represented by the line (11)-(10) is being cold rolled and is reduced in thickness to such an extent that its leaving surface will be as represented by the line (9)-(6). The reduction in thickness is then twice the distance (8)-(9), and the projected length of contact is the distance (10)-(8). If the rolling pressure produced in this operation is measured, we can compute the average pressure

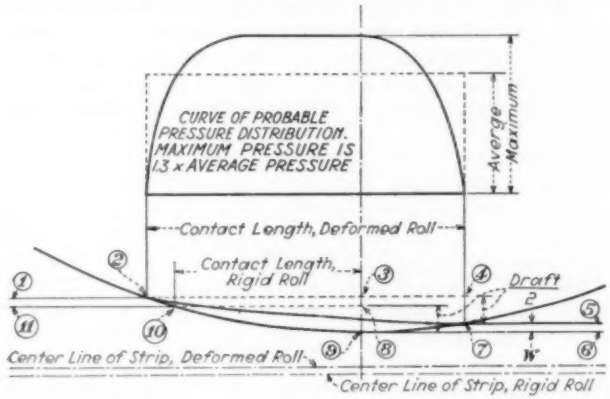

Fig. 9 Reduction in Thickness of the Strip by a Roll

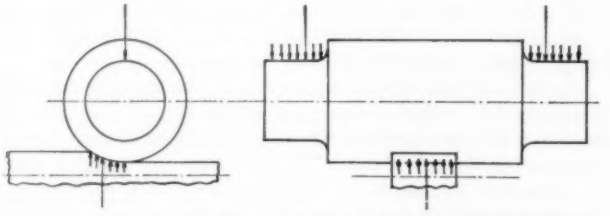

Fig. 11 Arrangement of Forces in Rolling

by dividing the measured load by the projected area of contact. The latter area is, of course, the length (10)-(8) multiplied by the width of the strip. In other words, if the width remains constant, the average pressure is inversely proportional to the length of contact. The average pressure calculated in this way for cold rolling steel is sometimes higher than 500,000 lb. per sq. in.

It is at once apparent that no roll material can remain rigid under such a pressure, and from that premise it follows that there must be deformation of the roll. Assume that the roll surface is flattened by some amount W, as shown in Fig. 9. In order to fulfill the same rolling conditions, the draft must be the same. If the leaving surface of the strip is represented by the line (7)-(5) and the new reduction (7)-(4) is made equal to the former reduction (9)-(8), the conditions will be fulfilled, and the entering surface of the strips will be as indicated by the line (1)-(2). The probable shape of the deformed roll surface is indicated by the curved line (2)-(7). Contact between the roll and strip must now begin at point (2), and extend considerably beyond the vertical center line to point (7). The length of contact therefore becomes (2)-(4), and from that increase over (10)-(8) it is obvious that the calculated average pressure will become very much less.

No really pertinent theory is in existence for this particular case of stress and strain. At the time of writing this paper, the engineers of one of the companies represented on the committee had undertaken the task of developing a satisfactory theory. At this time, it is believed that the most nearly applicable theory is that which was developed by Föppl for the compression of a cylinder between two flat plates. This theory can be found in Vol. 5 of Föppl's book, "Vorlesungen über Technische Mechanik." The arrangement of forces in this case is shown in Fig. 10, and in Fig. 11 is shown the arrangement of forces in rolling. It is evident from a comparison of Figs. 10 and 11 that the conditions in the two cases are somewhat different. With the certainty, however, that the rolls must be flattened under such high pressures, and in the absence of

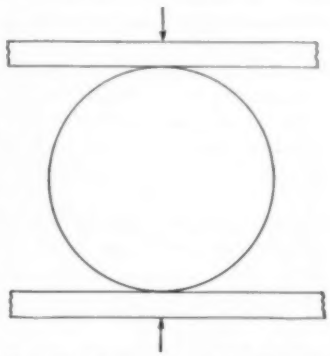

Fig. 10 Arrangement of Forces for a Cylinder Compressed Laterally Between Two Flat Plates

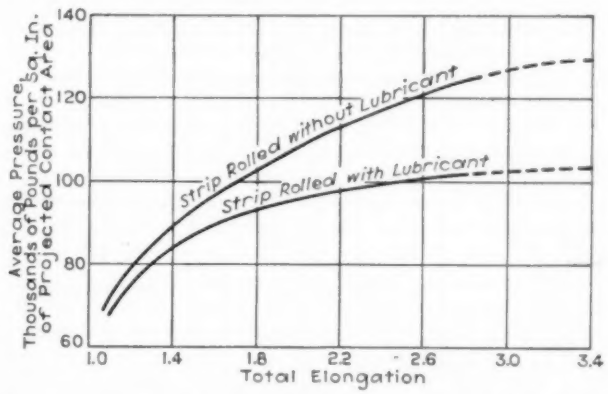

Fig. 12 Effect of Friction Between the Bar and the Rolls at High Compression Rates in Cold Rolling Mild Steel (0.10 Carbon) Based on Deformed Rolls

(For values of contact length/thickness between 6.0 and 17.0.)

a suitable theory to apply to the case, the average pressures based on deformed rolls were computed by means of equations developed from those given by Föppl. These equations, for cast-iron rolls, are:

$$W = 0.386 \times 10^{-7} \times F \left({}^{1}/_{3} + \log_e \frac{2a}{b_1} \right)$$

$$b_1 = 0.392 \times 10^{-3} \sqrt{Fa}$$

In these equations, F is the separating force per inch of width of the strip, a is the roll radius, and W is the deformation.

The curves of average pressure, based on deformed rolls, are shown in Figs. 12, 13, and 14, for the same types of steel and the same tests as those shown in Figs. 6, 7, and 8, respectively. The effect of roll deformation upon the average pressure is clearly shown by a comparison of the curves.

The effect of roll deformation is dependent upon the draft, upon the thickness and hardness of the strip being rolled, and upon the modulus of elasticity of the roll. As we have already noted, the average pressure can be calculated on the basis of rigid rolls. For comparison between cases in which the con-

ditions of draft, hardness, thickness, and roll material are similar, the latter basis is easier; and because of the uncertain accuracy of the foregoing equations in this application, the rigid-roll basis is preferable for such a comparison. In cases with dissimilar conditions of draft, hardness, thickness, or roll material, however, a comparison based on rigid rolls may produce very great error. In such cases, comparison should be made on the basis of deformed rolls because the possible inaccuracies of the formulas

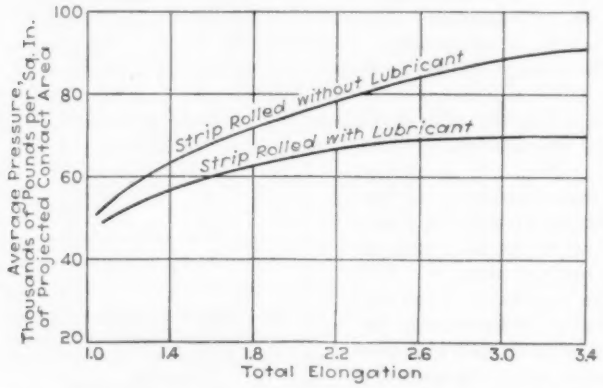

FIG. 13 EFFECT OF FRICTION BETWEEN THE BAR AND THE ROLLS AT HIGH COMPRESSION RATES IN COLD ROLLING HARD STEEL (0.63 CARBON) BASED ON DEFORMED ROLLS

(For values of contact length/thickness between 6.0 and 15.0.)

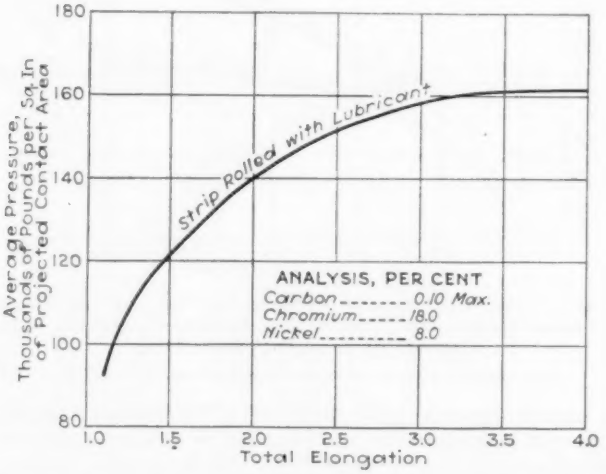

FIG. 14 PRESSURE FOR ALLOY STEEL COLD ROLLED UNDER TENSION AT HIGH COMPRESSION RATES WITH LUBRICANT BASED ON DEFORMED ROLLS

(For values of contact length/thickness between 2 and 5.)

are less than the acknowledged error of assuming rigid rolls. Further study of roll deformation and the consequent verification or modification of Föppl's formulas might well be undertaken by the Society's experts in Applied Mechanics.

It will be observed in Figs. 6, 7, 8, 12, 13, and 14 that for increasing values of total elongation the average pressure increases. This effect is due to change in internal friction of the steel. The hardness and tensile strength of steel are known to be increased by cold deformation, a familiar phenomenon which is called "flow-hardening." It is also known that these qualities are increased further with each successive amount of cold deformation. It is natural to expect that increased hardness of the steel being rolled would result in increased internal friction, and consequently in increased average pressure. Denoting by total elongation the amount of cold deformation to which the steel has been subjected without annealing, it is readily understood why the curves of the figures show increasing pressure with increasing total elongation. This point might be expressed by the statement that the average pressure depends upon the previous treatment of the metal.

The effect of compression rate is also due to internal friction, as was observed in the discussion on hot rolling. A further effect of internal friction is noted in the cold rolling of very thin sheets, in which case the increase in pressure is even more marked than in hot rolling, and for the same reasons.

The effect of external friction between the strip and the rolls can be observed by comparing the curves in Figs. 6, 7, 12, and 13. When a lubricant is introduced between the strip and the rolls, the force due to this friction is reduced and the pressure is decreased also. This also is a cumulative process, for the reasons mentioned in the previous discussion of friction.

The modulus of elasticity of the roll has an indirect effect upon the average pressure, the reason for which can now be made clear. A roll which has a low modulus of elasticity will have a greater deformation and a greater length of contact than a roll which has a high modulus of elasticity, all other effects being

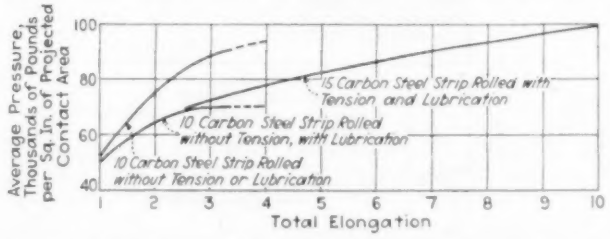

FIG. 15 COLD ROLLING MILD STEEL AT HIGH COMPRESSION RATES BASED ON DEFORMED ROLLS

equal. Increasing the length of contact produces increased friction between the rolls and the bar, with the result that the average pressure must also be increased.

It is believed that when a bar is rolled in a continuous mill and is subjected to tension between successive stands, the average pressure will be less than that which is found under corresponding conditions in a single stand. The reason for this belief is that the tension in the bar, acting in a direction opposite to that of the external friction force, cancels a portion of that force and thereby reduces the average pressure. However, when tension in the bar is used to draw the bar through the rolls of a single stand, and the rolls are driven solely by the friction between them and the bar (see Figs. 8 and 14), the average pressure appears to be approximately the same, for corresponding conditions, as that which is found in a single stand where rolling is done without tension. This fact is shown in Fig. 15, in which the two short curves are those of Fig. 12, drawn to a smaller scale, and in which the long curve represents steel of nearly the same composition cold rolled under tension. In studying these curves it should be noted that two different tests are represented, in which the methods of lubricating the strip and the extent of flow-hardening may differ.

The data upon which the curves shown are based are inadequate to complete our knowledge of rolling pressure. A definite qualitative relation between the average pressure and the factors which determine it has been found. The quantitative relations have been found for some conditions, but for a great many conditions these relations have yet to be determined. As we observed in the beginning, this knowledge is essential to intelligent design of anti-friction bearings for roll-necks. Additional test data are required, therefore, for the accomplishment of our purpose;

and the efforts of this committee will continue to be directed toward the fulfilment of that need.

The information contained herein is released with regret by the authors, because it is as yet incomplete. It is hoped, however, that the information, although incomplete, will be of assistance to those who have to deal with rolling-mill problems.

Discussion

S. M. Weckstein.[6] The paper is interesting and is of much wider scope than appears from a casual reading. To familiarize you further with the object of this paper and the work of the committee, the writer would like to make the following statements:

A few years ago the subject of the application of anti-friction bearings in steel mills and especially in the rolling mills themselves was brought up. At that time very little information was had by the bearing manufacturers and to a large extent by the mill builders and rolling mills as to the actual loads encountered in rolling steel and non-ferrous alloys.

The various bearing manufacturers as well as mill builders independently conducted a number of tests by means of hydraulic cylinders, Brinell plates, and other approved methods to determine these loads, and on the basis of these tests submitted bearing recommendations which were adopted and which have proved to be satisfactory in quite a large number of cases. There was no unified effort, however, to study this problem and to work up standards on which to base recommendations. Through the efforts of the A.S.M.E. and through the able assistance of Professor Trinks, a committee was formed to investigate this subject. This paper covers generally the few preliminary reports which have been made by the committee. The work which the committee has done so far is merely a small beginning of the work which is ahead of them. All of the bearing manufacturers, the mill builders, and quite a few of the rolling mills are cooperating with the committee in extending this information.

Just recently the Timken Roller Bearing Company finished a complete series of tests on the various rolling mills in its plant. Preliminary results of these tests have already been published by our Mr. Waldorf in recent issues of *The Electrical Iron & Steel Engineer*.

Information is now being turned over to the committee for further analysis, and these data will be included in forthcoming reports of the committee. Since this test covers the rolling of various alloy steels in a 35-in. blooming mill and 28- and 22-in. bar mills and in a continuous 10-in. stand 18- to 10-in. bar mill, and was also run on plain bearings and on Timken bearings, the information obtained from this test should be quite a contribution to the industry.

The cooperation of all the rolling mills is requested in assisting and further increasing the sources of information for the committee. As a representative of one of the bearing companies which is interested in this work, the writer feels quite certain that the data which this committee will compile will be not only of extreme value to the bearing manufacturers, but will also be a great help to the mill builders and mill operators. The application of anti-friction bearings in rolling mills is at the present time in its infancy, and the field is important enough to deserve everybody's closest study.

W. Trinks.[7] As a co-author, I should not be called upon to discuss the paper. Nevertheless a few remarks are in order. The data presented in the paper apply only to iron and steel. Data on other metals have also been collected, but were not included in this paper, because of its being read under the auspices of the Iron and Steel Division. It should be mentioned that the investigation of the forces involved in rolling is only the first step. When that investigation shall have been completed, the next step consists in analyzing the stresses which occur in the roll body and the roll neck. The committee is already at work on this problem, and hopes to have results of great interest to present in the near future. All iron and steel works in possession of test data have willingly contributed them. Also the manufacturers of metals other than iron and steel have, with one exception, been very willing to detail their experience.

The work of the committee is financed by contributions of $200 each from companies interested in the work. No difficulty was attached to securing contributions.

With regard to the application of high-duty anti-friction bearings, the following may be remarked. A few months ago the writer had the opportunity to go through several mills employing such bearings. In one of the mills the superintendent led the way to the "boneyard" and showed a large number of bearings which had failed in service. He said that in each case failure could be traced back to the failure of an individual roller and that the investigation of that roller showed that internal cracks or other defects were responsible. It therefore appears that it would be advisable to test each individual roller, either by X-ray analysis or by magnetic analysis, so as to positively eliminate the danger of internal defects.

The cost of high-duty anti-friction bearings is so great and the cost of a shutdown is so great that the cost of inspection of each individual roller by one of the cited methods should be only a small fraction, a very small fraction indeed, of the total cost of the bearing.

J. L. Young.[8] Professor Trinks raised the question that the various bearing manufacturers should do everything within their power to prevent flaws and defects in the rolls of their bearings in order to eliminate the difficulties he cited.

He referred especially to his recent trip to a steel mill in the Chicago district where he saw a number of failed straight-roll back-up roll-neck bearings from a four-high mill and the manager of that plant stated that in nearly every case they could trace the failure to the breakage of the rolls and to a defect or flaw in one or more rolls in that bearing. He suggested the use of the X-ray test or the Sperry magnetic test as a final inspection of bearings to determine these defects.

The point raised by Professor Trinks is a good one, but the writer believes there is another angle from which to approach the subject of defects in the rolls of large bearings, for the type of steel and method of heat treatment have as much or more to do with the elimination of defects as the proposed extra final inspection to catch these defects. The rolls referred to were made of a high-carbon chrome-type steel.

The Timken Company has experimented for years with the object in view of making the best possible bearing. Based upon those experiments we have arrived at a conclusion that a properly carburized and heat-treated large section bearing of proper analysis is superior to a bearing of similar section made of high-carbon chrome steel.

These are certain inherent difficulties that accompany the processing and heat-treating of large sections of high-carbon chrome steel. They are to some extent eliminated by the use

of a proper carburizing steel that will give the same hardness for the bearing surface that is possible to obtain with high-carbon chrome steel and at the same time give a tough and softer core of proper gradation. This will eliminate the brittleness of the entire roll.

Based upon experiments, the Timken Company has adopted a nickle-chrome carburizing steel that when properly carburized and heat-treated gives the desired hardness gradation. The success of large section Timken bearings in steel mills is sufficient proof that this method is correct.

The original bearings on two installations of four-high mills in the Pittsburgh district are now entering their fifth year of successful service.

We are now producing a quantity of bearings for a new four-high mill, to be located in the Chicago district, that will be the largest rolling-mill bearings ever made. The neck diameter will be $29^1/_2$ in. The bearing will be $46^1/_2$ in. and the length will be 29 in. Each bearing will weigh about $3^1/_2$ tons without the chock.

Instead of the X-ray or magnetic methods of final inspection, the Timken Company has developed a radio testing machine that is now used extensively throughout the automotive industry and which apparatus gives us a final check on the condition of the bearings from a standpoint of surface defects that cannot be seen by the visual method. This machine is nothing more than a radio that transmits the noise developed by rotating a bearing under load to the dial of a galvanometer. If there is any sort of a surface defect that may interfere with the proper functioning of the bearing, it will cause an over-noise that will be transmitted through the radio to the galvanometer.

The Timken Company is vitally interested in manufacturing the best possible anti-friction bearings for steel mill service, and if by the use of either the X-ray or the magnetic methods of testing we can better our product, we will gladly resort to those methods, but so far we feel that the thirty-two or more inspections that a bearing receives in our plant before it is shipped to the customer allows the production of a bearing that is as nearly correct as is commercially possible to produce.
